DUAL TECHNIQUES FOR SCHEDULING ON A MACHINE WITH VARYING SPEED*

NICOLE MEGOW† AND JOSÉ VERSCHAE‡

Abstract. We study scheduling problems on a machine with varying speed. Assuming a known speed function we ask for a cost-efficient scheduling solution. Our main result is a polynomial-time approximation scheme (PTAS) for minimizing the total weighted completion time in this setting. This also implies a PTAS for the closely related problem of scheduling to minimize generalized global cost functions, that is, the problem $1||\sum w_j f(C_j)$. The key to our results is a reinterpretation of the problem within the well-known *two-dimensional Gantt chart*: instead of the standard approach of scheduling in the *time dimension*, we construct scheduling solutions in the *weight dimension*. This allows structural simplifications of the instance and optimal solutions, based on which we can defer the concern of speed to the evaluation of cost in a dynamic programming framework. We also consider a dynamic problem variant, where the decision upon the speed is part of the problem and we are interested in the trade-off between scheduling cost and speed-scaling cost, which is typically the energy consumption. We observe that the optimal order is independent of the energy consumption and that the problem can be reduced to the setting where the speed of the machine is fixed, and thus admits a PTAS. Furthermore, we provide a fully polynomial-time approximation scheme for the NP-hard problem variant in which the machine can run only at a fixed number of discrete speeds. Finally, we show how our results can be used to obtain a $(2+\varepsilon)$-approximation for scheduling preemptive jobs with release dates on multiple identical parallel machines.

Key words. scheduling, approximation algorithms, speed scaling, power management, generalized min-sum cost functions, nonavailability periods

DOI. 10.1137/16M105589X

1. Introduction.

In several computation and production environments we face scheduling problems in which the speed of resources may vary. We distinguish mainly two types of varying-speed scenarios: one in which the speed is a *given* function of time and another *dynamic* setting in which deciding upon the processor speed is part of the scheduling problem. The first setting occurs, e.g., in production environments where the speed of a resource may change due to overloading, aging, or in an extreme case it may be completely unavailable due to maintenance or failure. The dynamic setting finds application particularly in modern computer architectures, where speed-scaling is an important tool for power management. Here we are interested in the trade-off between the power consumption and the quality-of-service. Both research directions—scheduling on a machine with given speed fluctuation as well as scheduling including speed-scaling—have been pursued quite extensively, but seemingly separately from each other.

The main focus of our work and the main technical contribution lie in the setting with a given speed function. We consider the problem of scheduling to minimize the sum of weighted completion times $\sum_j w_j C_j$, a standard measure for quality-of-service. We present a polynomial-time approximation scheme (PTAS) for this problem which is best possible unless P=NP. This result translates directly to the equivalent problem $1|\,|\sum_j w_j f(C_j)$ (with f nondecreasing), that is, the problem of scheduling on a machine with unit speed but with a nonlinear objective function $\sum_j w_j f(C_j)$. In addition, we draw an interesting connection to the dynamic model which allows us to transfer some of our techniques to this setting.

Standard scheduling techniques rely on delaying jobs or rounding and approximating processing requirements. Such approaches generally fail on varying-speed machines. The reason is that the slightest error introduced by rounding might provoke an unbounded increase in the solution cost. Similarly, adding any amount of idle time to the machine might be fatal. To illustrate this, consider a machine with unit processing speed which reduces its speed to zero during the interval $[d, D]$, with $D \gg d$. Now, a single job j with processing time d can obviously complete by time d. However, any rounding up or delay will cause a dramatic change in the completion time of j and, thus, may provoke a large change in the overall cost. This would be the case if the job has a relatively large weight, but it will not happen if the weight of this job is small relative to the total weight of the instance.

At a high level, we determine the flexibility for modifying our solution depending on the weight of unfinished jobs at a given point in time. Following our example, assume that the job j with processing time d has a weight $w \leq \varepsilon W$, where W is the total weight of the instance. Assume further that after j, our solution processes a second job, j', of processing time p and weight, say, $W/2$ or less. Then we observe that the remaining weight after j and j' are completed is still $\Omega(W)$. Thus, swapping the two mentioned jobs cannot increase the cost of the total solution dramatically. The reason is that the total cost of the solution is at least $\Omega(W \cdot (D+p))$, and thus, even if the cost increases by $w(D+p) = \varepsilon W(D+p)$, this error is small relative to the total cost of the solution.

The previous example suggests that the remaining weight may give valuable information about when jobs are interchangeable without increasing the cost too much and, thus, how much flexibility we have in a solution independently of the speed function. In order to exploit this in a PTAS we need a very precise and flexible approach to handle such information. We use the well-known geometric view of the min-sum scheduling problem in a *two-dimensional Gantt chart*, an interpretation originally introduced by Eastman, Even, and Isaacs [13]. We deviate from the standard view of scheduling in the *time dimension* and switch to scheduling in the *weight dimension*. The high-level approach is simple: we design a dynamic program (DP) that computes an optimal schedule in the weight dimension which then can be directly translated into a true schedule (in time). The key contribution is that our DP needs to take the speed into account only when computing the value of a DP state whereas any partitioning and rounding can be done only in the weight dimension and, most importantly, independently of the speed.

1.1. Previous work. Research on scheduling on a machine of given varying speed has mainly focused on the special case of scheduling with nonavailability periods; see, e.g., [12, 20, 21, 25]. Despite a history of more than 30 years, only recently was the first constant approximation for $\min \sum w_j C_j$ derived by Epstein et al. [14]. In fact, their $(4+\varepsilon)$-approximation computes a universal sequence which has the same

guarantee for any (unknown) speed function. For the setting with release dates, they give an approximation algorithm with the same guarantee for any given speed function. If the speed is assumed to be nondecreasing (and the release dates are trivial), there is an efficient PTAS [27]. In this case the complexity status remains open, whereas for general speed functions the problem is strongly NP-hard, even when for each job the weight and processing time are equal [30].

The problem of scheduling on a machine of varying speed is equivalent to scheduling on an ideal machine (of constant speed) but minimizing a more general global cost function $\sum w_j f(C_j)$, where f is a nondecreasing function. In this identification, $f(C)$ denotes the time that the varying-speed machine needs to process a work volume of C [16]. The special case of only nondecreasing (nonincreasing) speed functions corresponds to concave (convex) global cost functions. In a recent work, Höhn and Jacobs [16] give a formula for computing tight guarantees for Smith's rule for any convex or concave function f. They also show that the problem for an increasing piecewise linear cost function is strongly NP-hard even with only two different slopes, and so is our problem when the speed function takes only two distinct values.

Even more general min-sum cost functions have been studied, where each job may have its individual nondecreasing cost function. For this setting, Cheung et al. [11] give the currently best known approximation algorithm with a worst-case factor of $4+\varepsilon$. For the more complex setting with release dates, Bansal and Pruhs [5] present a randomized $\mathcal{O}(\log\log P)$-approximation, where P is the ratio between the largest to smallest processing time. Clearly, these results translate also to the setting with varying machine speed.

Scheduling with dynamic speed-scaling was initiated in the work by Yao, Demers, and Shenker [31] and became a very active research field in the past fifteen years. Most work focuses on scheduling problems where jobs have release dates and deadlines and the objective is to minimize energy consumption. We refer to [2, 17] for an overview. Closer to our setting is the work initiated by Pruhs, Uthaisombut, and Woeginger [24] who present a polynomial algorithm for minimizing the total flow time given an energy budget if all jobs have the same work volume. This work is later continued by many others; see, e.g., [3, 6, 9] and the references therein. Most of this literature is concerned with online algorithms to minimize total (or weighted) flow time plus energy. The minimization of the weighted sum of completion times plus energy has been considered recently. Angel, Bampis, and Kacem [4] derive constant approximations for nonpreemptive models with unrelated machines and release dates. Carrasco, Iyengar, and Stein [8] obtain similar results even under precedence constraints.

For the general objective of speed-scaling with an energy budget as considered in this paper, Angel, Bampis, and Kacem [4] show a randomized $(2+\varepsilon)$-approximation slightly exceeding the energy budget for nonpreemptive scheduling on unrelated machines with release dates. The bounds given for scheduling cost and the budget excess are satisfied only in expectation.

1.2. Our results. We give several best possible algorithms for problem variants that involve scheduling to minimize the total weighted completion time on a single machine that may vary its speed.

Our main result is an efficient PTAS (section 3) for scheduling to minimize $\sum w_j C_j$ on a machine of varying speed (given by an oracle). This is best possible since the problem is strongly NP-hard, even when the machine speed takes only two distinct values [16]. Our results generalize previous results such as a PTAS on a

machine with only *nondecreasing* speeds [27] and fully polynomial-time approximation schemes (FPTASs) for only *one* nonavailability period [18, 19].

As mentioned before, standard scheduling techniques rely on delaying jobs or rounding processing requirements, which, in general, must fail on varying-speed machines. Our techniques completely avoid this difficulty by a change of paradigm. To explain our ideas it is helpful to use a two-dimensional (2D) Gantt chart interpretation [13]; see section 2. As observed before, e.g., in [15], we obtain a *dual* scheduling problem by looking at the y-axis in a 2D-Gantt chart and switching the roles of the processing times and weights. In other words, a dual solution describes a schedule by specifying the remaining weight of the system at the moment a job completes. This simple idea avoids the difficulties on the time axis and allows one to combine old with new techniques for scheduling on the weight axis.

In the case that an algorithm can set the machine at arbitrary speeds, we show in section 4 that the optimal scheduling sequence is independent of the available energy. This follows by analyzing a convex program that models the optimal energy assignment for a given job permutation. A similar observation was made independently by Vásquez [29] in a game-theoretic setting. We show that computing this universal optimal sequence corresponds to the problem of scheduling with a particular concave global cost function, which can be solved with our PTAS mentioned above, or with a PTAS for nondecreasing speed [27]. Interestingly, this reduction relies again on a problem transformation from time space to weight space in the 2D Gantt chart. For a given scheduling sequence, we give an explicit formula for computing the optimal energy (speed) assignment. Thus, we have a PTAS for speed-scaling and scheduling for a given energy budget. We remark that the complexity of this problem is open.

In many applications, including most modern computer architectures, machines are only capable of using a given number of discrete power (speed) states. We provide in section 5 an efficient PTAS for this complex scenario. This algorithm is again based on our techniques relying on dual schedules. Furthermore, we obtain a $(1+\varepsilon)$-approximation of the Pareto frontier for the energy-cost bicriteria problem. On the other hand, we show that this problem is NP-hard even when there are only two speed states. We complement this result by giving an FPTAS for a constant number of available speeds.

In section 6 we consider a more complex scheduling problem in the speed-scaling setting: jobs have individual release dates and must be scheduled preemptively on m identical parallel machines. We notice that our PTAS results can be utilized to obtain a $(2+\varepsilon)$-approximation for scheduling preemptive jobs with nontrivial release dates on identical parallel machines. Here, we apply our previous results to solve a *fast single machine relaxation* [10] combined with a trick to control the actual job execution times. Then, we keep the energy assignments computed in the relaxation and apply *preemptive list scheduling* on parallel machines respecting release dates. We note that our deterministic algorithm guarantees that any solution it obtains has cost within a factor of $2+\varepsilon$ and it meets the energy budget. This cannot be guaranteed in the previous nonpreemptive result for our objective function with energy budget in [4].

This paper expands considerably the extended abstract that appeared in the proceedings of *ICALP* 2013 [22]. Among others, this new version contains complete proofs, full presentation of our techniques, and new approximation results for more general scheduling problems with release dates and identical parallel machines (section 6).

2. Model, definitions, and preliminaries.

2.1. Problem definition. We consider two types of scheduling problems. In both cases we are given a set of jobs $J = \{1, \dots, n\}$ with work volumes (i.e., processing time at speed 1) $v_j \geq 0$ and weights $w_j \geq 0$. We seek a schedule on a single machine, described by a permutation of jobs, that minimizes the sum of weighted completion times. The speed of the machine may vary—this is where the problems are distinguished.

In the problem *scheduling on a machine of given varying speed* we assume that the speed function $s : \mathbb{R}_+ \to \mathbb{R}_+$ is given implicitly by an oracle. Given a value v, the oracle returns the first point in time when the machine can finish v units of work. That is, for a speed function s the oracle returns the value

$$f(v) := \inf \left\{ b > 0 : \int_0^b s(t)dt \geq v \right\}. \tag{2.1}$$

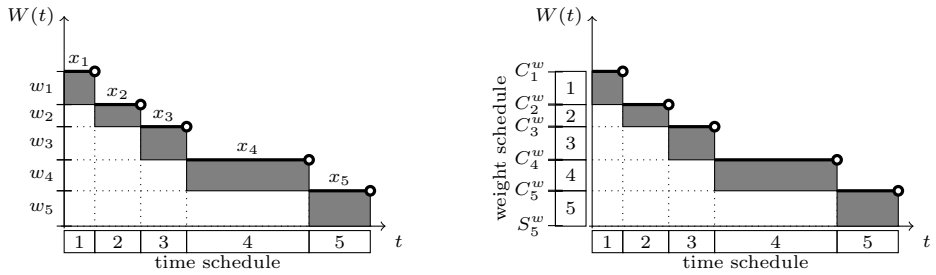
Here we are implicitly assuming that s is integrable. Using the oracle, we can compute for a given order of jobs the execution and completion times and thus the total cost of the solution. We additionally must ensure that the numbers returned by the oracle can be handled efficiently. To avoid extra technical difficulties, we call an algorithm efficient if it runs in time polynomial in the input size and the largest encoding size of a number returned by the oracle.

In the problem *scheduling with speed-scaling* an algorithm determines not only a schedule for the jobs but will also decide at which speed $s \geq 0$ the machine will run at any time. Running a machine at a certain speed requires a certain amount of power. Power is typically modeled as a monomial (convex) function of speed, $P(s) = s^\alpha$ with a small constant $\alpha > 1$. Given an energy budget E, we ask for the optimal power (and thus speed) distribution and corresponding schedule that minimizes $\sum_j w_j C_j$. More generally, we are interested in quantifying the trade-off between the scheduling objective $\sum_j w_j C_j$ and the total energy consumption, that is, we aim for computing the Pareto curve for the bicriteria minimization problem. We consider two variants of speed-scaling: if the machine can run at an arbitrary speed level $s \in \mathbb{R}_+$, we say that we are in the *continuous-speed* setting. On the other hand, if that machine can only choose among a finite set of speeds $\{s_1, \dots, s_\kappa\}$ we are in the *discrete-speed* environment.

In both of our settings our solution concept is a permutation of jobs. Notice that this is no restriction since preemption or idle times cannot reduce the cost of the solution.

2.2. From time space to weight space. For a schedule $\mathcal{S}$, we let $S_j(\mathcal{S})$ and $C_j(\mathcal{S})$ denote the starting time and completion time, respectively, of job j. Furthermore, we let $W^{\mathcal{S}}(t) = \sum_{j:C_j>t} w_j$ denote the total weight of all jobs that complete in $\mathcal{S}$ strictly after t. Note that by definition $W^{\mathcal{S}}(t)$ is right-continuous, i.e., if $C_j(\mathcal{S}) = t$, the weight of j does not count towards the remaining weight $W^{\mathcal{S}}(t)$. To simplify notation, whenever $\mathcal{S}$ is clear from the context we will omit it and write C_j and $W(t)$ instead.

In Figure 1(a), we show a typical schedule with five jobs in the well-known 2D Gantt chart representation. Given some speed function and a schedule as depicted on the x-axis, each job j is represented by a rectangle with a length corresponding to the processing time x_j (not to be confused with the processing volume) and a height corresponding to the job weight. The schedule on the x-axis is described explicitly



(a) 2D Gantt chart of schedule with 5v jobs with the function of remaining weights (bold).

(b) Same figure as (a) additionally depicting the weight schedule and the used notation.

FIG. 1. *2D Gantt chart.*

by giving the completion time C_j of each job j. We refer to this standard schedule as *time schedule*. The function in bold is the remaining weight function $W(\cdot)$ of the schedule. Notice that, in general, the cost of a schedule equals the area under the remaining weight curve, that is,

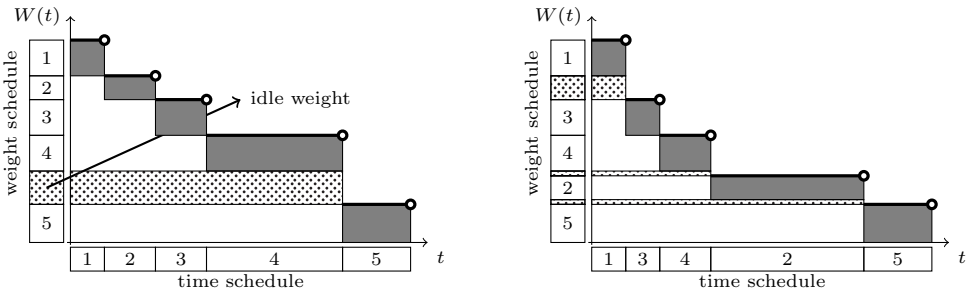
$$\sum_{j \in J} w_j C_j = \int_0^\infty W(t)dt. \tag{2.2}$$

Weight schedule. A key idea in this paper is as follows: instead of describing a scheduling solution by specifying completion times in a time schedule, we describe it in terms of the remaining weight function W. Consider Figure 1(b). It depicts the same 5-job instance with the same time schedule as Figure 1(a). On the y-axis there is given a dual schedule which we call the *weight schedule*. Informally speaking, it is obtained by projecting the 2D-Gantt chart on the y-axis. In the resulting weight schedule each job has a length corresponding to its weight, and the scheduling order, from bottom to top, is the reverse order of the time schedule.

In this paper we produce scheduling solutions by constructing a weight schedule from bottom to top on the weight axis, that is, we essentially schedule along the weight axis. We use a notation that imitates the standard notation when scheduling on the time axis and indicate by superscript w that we refer to the weight space. We call the point on the y-axis at which a job j starts, the *starting weight* and denote it by S_j^w. Similarly, we define the *completion weight* of j as $C_j^w := S_j^w + w_j$. Observe that in Figure 1(b) we have $S_5^w = 0, C_5^w = S_4^w = w_5, C_4^w = S_3^w = w_5 + w_4$, etc.

With this notation, we formally define a weight schedule for a set of jobs with nonnegative weights as a collection of completion weights $C_j^w \in \mathbb{R}_+$ with corresponding starting weights $S_j^w = C_j^w - w_j \geq 0$, where the intervals $[S_j^w, C_j^w)$ are pairwise disjoint. Notice that the value S_j^w is not necessarily implied by an underlying time schedule. The reason is that in a weight schedule, as defined above, we may keep some idleness between jobs; see the example in Figure 2(a). We elaborate on this below.

Also notice that in nonidling schedules, the starting weight of a job j in the weight schedule corresponds to the value of W at the time that j completes in the time schedule. Similarly, the completion weight of j is the total remaining weight of all jobs completing by or after C_j in the time schedule. Hence, a weight schedule immediately defines a unique nonpreemptive time schedule without idle time: simply order the jobs by decreasing completion weights. Similarly, each time schedule defines a unique nonidling weight schedule by defining S_j^w as the value of the remaining weight at the time j completes.



(a) Scheduling solution with artificially added idle weight; the time schedule has no idle time.

(b) New situation after placing job 2 in idle weight and decreasing its completion weight.

FIG. 2. *2D Gantt charts and idle weight.*

Idle weight. While we restrict ourselves to schedules without idle time, it will be convenient to allow idleness in the corresponding weight schedules. In Figure 2(a), there is shown a weight schedule with $S_5^w = 0, C_5^w = w_5$, and $S_4^w > C_5^w$. We say that $w \in \mathbb{R}_+$ is an *idle weight* if $w \notin [S_j^w, C_j^w]$ for all j. In the weight schedule depicted in Figure 2(a), each w in the hatched interval (C_5^w, S_4^w) is an idle weight, as no interval $[S_j^w, C_j^w]$ intersects it. Notice, that for each (nonidling) time schedule there is an infinite number of corresponding weight schedules.

We express the cost of a weight schedule as follows. Consider a weight schedule with completion weights $C_1^w \geq \cdots \geq C_n^w$ and the corresponding (unique) time schedule without idle times with completion times $C_1 \leq \cdots \leq C_n$. To simplify notation let $C_{n+1}^w = 0$. Then we define the cost of the weight schedule as $\sum_{j=1}^n (C_j^w - C_{j+1}^w) C_j$. It is easy to check, even from the 2D Gantt chart, that this value equals $\sum_{j=1}^n x_j^{\mathcal{S}} C_j^w$, where $x_j^{\mathcal{S}}$ is the execution time of job j (in time space). For example, see Figure 2(a), and notice that the cost of the weight schedule equals the integral of the bold curve, while the cost of the corresponding time schedule, given by (2.2), equals that integral minus the hatched area under the curve. More generally, the cost of the weight schedule equals the cost of the time schedule, see (2.2), if and only if the weight schedule does not have any idle weight. In general, the cost of the weight schedule can only *overestimate* the cost of the corresponding schedule in time space (without idle time).

Advantages. Working with weight schedules has a number of technical advantages when scheduling on a machine of varying speed. In particular, time schedules are highly sensitive to machine-speed variations. The execution time of a job may change drastically even when only slightly shifting a job. Standard scheduling techniques such as rounding and guessing in the time axis are hard to control in how they affect the cost of a solution. On the other hand, in a weight schedule the length of a job, that is, its weight, is fixed and we can round it and create idle weight without provoking an unbounded increase in the cost.

By adding idle weight, we gain flexibility which allows us, for example, to delay one or more jobs in the time schedule without further increasing the cost. Consider Figure 2(a) to exemplify this. Here, job 2 fits in the idle weight between jobs 4 and 5 (hatched area). A new solution obtained by moving job 2 to this idle weight, and thus, decreasing its completion weight, is shown in Figure 2(b). This operation delays job 2 in the time schedule, while it schedules jobs 3 and 4 earlier. However, the total cost of the weight schedule, i.e., the area under the curve, decreases.

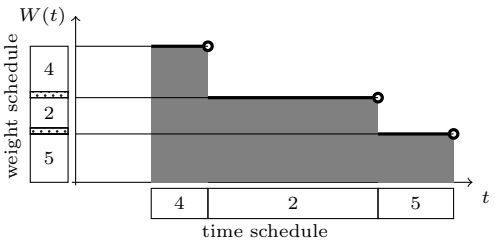


FIG. 3. *Partial weight schedule. 2D Gantt chart showing a partial weight schedule of three jobs and its corresponding time schedule. The gray area corresponds to the cost of this partial solution.*

We will make extensive usage of this property which we formalize in the following observation and which can be derived directly from the 2D Gantt chart.

Observation 2.1. Consider a weight schedule $\mathcal{S}$ with enough idle weight so that decreasing the completion weight of some job j, while leaving the rest untouched, yields a feasible weight schedule. This operation does not increase the cost of the weight schedule $\mathcal{S}$. Indeed, notice that job j is the only job for which its completion *time* might increase. However, this does not increase the cost of the weight schedule since the extra cost is dominated by the area induced by the idle weight in the original schedule.

3. A PTAS for scheduling on a machine with given speeds. In this section we give a PTAS for minimizing $\sum_j w_j C_j$ on a single machine with a given speed function. Our algorithm is a DP that constructs a weight schedule from bottom to top along the weight axis which can be turned into a regular time schedule by scheduling jobs nonpreemptively in the reverse order, i.e., in decreasing order of completion weights.

The overall idea of the DP is simple. Let $w(S) := \sum_{j\in S} w_j$ denote the total weight of jobs in set S. For any $u \in \mathbb{Z}$, we define a family of job sets $\mathcal{F}_u := \{S \subseteq J : w(S) < (1+\varepsilon)^u\}$. That is, a set S belongs to $\mathcal{F}_u$ if and only if we can feasibly schedule all jobs in S within weights 0 and $(1+\varepsilon)^u$. Our DP computes the optimal solution for scheduling set $S \in \mathcal{F}_u$ on the weight axis during interval $[0, (1+\varepsilon)^u)$ by guessing the optimal subset $S' \in \mathcal{F}_{u-1}$ with $S' \subseteq S$, of jobs processed in the weight interval $[0, (1+\varepsilon)^{u-1})$.

The total cost of a partial weight schedule $\mathcal{S}$ for set S is defined as $\sum_{j\in S} x_j^{\mathcal{S}} C_j^w$, where $x_j^{\mathcal{S}}$ is the execution time of job j; cf. the gray area in Figure 3. Observe that we can determine these execution times of the first jobs in a partial weight schedule (last jobs in the corresponding time schedule) since we can compute a priori the *makespan* of the final solution, that is, the completion time of the last job on the time axis. Indeed, since there is no idle time, the makespan equals the total time it takes to execute all jobs, i.e., $f(\sum_j v_j)$, and can be computed by calling the oracle once. It is not hard to estimate the optimal cost for subset S given the optimal cost for S', which is given by the dynamic programming table. Within a $(1+\varepsilon)$ factor, this cost is $\sum_{j\in S'} x_j^{\mathcal{S}} C_j^w + (1+\varepsilon)^u \sum_{j\in S\setminus S'} x_j^{\mathcal{S}}$, and $\sum_{j\in S\setminus S'} x_j^{\mathcal{S}}$ is completely determined by the total processing volumes of S and S'. With this, computing the value of the dynamic programming table for set S reduces to comparing the corresponding costs over all possible sets $S' \subseteq S$ for $S' \in \mathcal{F}_{u-1}$.

Implementing this approach has a crucial problem, namely, a set $\mathcal{F}_u$ might have exponential size. The bulk of our technical contribution consists in decreasing the size $\mathcal{F}_u$ to a constant with only a minor impact on the objective function value. This

will be done using a series of rounding and simplification techniques that show the existence of a highly structured near-optimal weight schedule. This structured weight schedule is then used to construct the compact versions of sets $\mathcal{F}_u$, which we call $\tilde{\mathcal{F}}_u$. A crucial technique for doing this is the creation of idle weight via weight stretching, which allows us to use Observation 2.1 to shift jobs without increasing further the cost.

The construction of sets $\tilde{\mathcal{F}}_u$ has two steps. First, we classify jobs as *light* or *heavy* depending on their weight and position in the schedule. We say that a job is light in a given schedule with starting weight S_j^w if $w_j \leq \varepsilon^3(1+\varepsilon)S_j^w$. Intuitively, light jobs can be treated as infinitesimally small jobs. We show that, given any weight schedule for heavy jobs, light jobs can be scheduled optimally if we first sort them nonincreasingly by v_j/w_j, that is, the reverse order of the well-known Smith order [26], and then assign them greedily.

Additionally, for each job j, heavy or light, we compute an interval $[r_j^w, d_j^w)$ with two properties: (i) the interval is sufficiently small, i.e., $d_j^w/r_j^w \in \mathcal{O}(\text{poly}(1/\varepsilon))$, and (ii) there exists a near optimal weight schedule where all jobs lie within $[r_j^w, d_j^w)$. With this in place we can compute sets $\tilde{\mathcal{F}}_u$. Notice that then each job with $d_j^w < (1+\varepsilon)^u$ will belong to every set in $\tilde{\mathcal{F}}_u$, and every job with $r_j^w \geq (1+\varepsilon)^u$ will not belong to any set in $\tilde{\mathcal{F}}_u$. Hence, the enumeration of sets $\tilde{\mathcal{F}}_u$ only needs to consider jobs j with $(1+\varepsilon)^u \in (r_j^w, d_j^w]$. To enumerate small jobs, the fact that they can be scheduled greedily implies that we must only decide what is the smallest ratio v_j/w_j of a job scheduled before $(1+\varepsilon)^u$. Using rounding techniques, we can assume that the number of different choices is $\text{poly}(1/\varepsilon)$. Moreover, after rounding the weights to powers of $(1+\varepsilon)$, the number of different weights of heavy jobs with $(1+\varepsilon)^u \in (r_j^w, d_j^w]$ can be shown to be at most $\text{poly}(1/\varepsilon)$, creating $\text{poly}(1/\varepsilon)$ classes of jobs. For each of these classes, an optimal solution will sort them by processing volume (independently of the machine speed!). Furthermore, we will show that our construction of intervals $[r_j^w, d_j^w)$ implies that the number of jobs within each class is $\text{poly}(1/\varepsilon)$. Hence, for a given class we must consider a constant number of different choices. Combining all our choices, we obtain that the size of $\tilde{\mathcal{F}}_u$ is at most $2^{\text{poly}(1/\varepsilon)}$.

One major advantage of this approach is that the construction of compact sets $\tilde{\mathcal{F}}_u$ is done completely in the weight axis, and thus it is independent of the speed function. Thus, we only need to call the oracle, and weigh in the effect of the speed function, when constructing the dynamic programming table. Additionally, the fact that $\tilde{\mathcal{F}}_u$ is independent of the speed will allow us to reuse this construction in the variable-speed setting for speed-scaling, and it might be useful for related problems.

The structure of the rest of this section is as follows:

- In subsection 3.1, we explain our DP which initially takes exponential time.
- In subsection 3.2, we apply some general rounding techniques known from standard scheduling on the time axis and generate idle weight.
- Subsection 3.3 shows that a greedy approach suffices to schedule light jobs.
- In subsection 3.4 we compute the intervals $[r_j^w, d_j^w)$ for each j.
- Finally, in subsection 3.5 we show how to compute the compact subsets $\tilde{\mathcal{F}}_u$ by using the intervals $[r_j^w, d_j^w)$ together with the fact that light jobs can be scheduled greedily.

3.1. Dynamic program. We describe our dynamic programming approach and construct a dynamic programming table with exponentially many entries.

Consider a subset of jobs $S \subseteq J$ and a partial schedule of S in the weight space. In our DP, S will correspond to the set of jobs at the beginning of the weight schedule,

i.e., if $j \in S$ and $k \in J \setminus S$ then $C_j^w < C_k^w$. A partial weight schedule $\mathcal{S}$ of jobs in S implies a schedule in time space with the following interpretation. Note that the makespan of the time schedule is completely defined by the total work volume $\sum_j v_j$. We impose that the last job of the schedule, which corresponds to the first job in $\mathcal{S}$, finishes at the makespan. This uniquely determines a value of C_j for each $j \in S$, and thus also its execution time $x_j^{\mathcal{S}}$. The total cost of this partial schedule is defined to be $\sum_{j \in S} x_j^{\mathcal{S}} C_j^w$. See Figure 3 for a pictorial example; the gray area defines the cost of the partial weight schedule.

Consider a discretization of the weight space defined by intervals $I_u = [(1+\varepsilon)^{u-1}, (1+\varepsilon)^u)$ for $u \in \{1, \ldots, \nu\}$, where $\nu := \lceil \log_{1+\varepsilon} \sum_{j \in J} w_j \rceil$. We denote the length of each interval I_u as $|I_u| := \varepsilon(1+\varepsilon)^{u-1}$, and recall that for a job set S we denote by $w(S)$ its total weight, $\sum_{j \in S} w_j$. Recall that $\mathcal{F}_u := \{S \subseteq J : w(S) < (1+\varepsilon)^u\}$, that is, a set $S \in \mathcal{F}_u$ is a potential set of jobs to be processed in weight interval $[0, (1+\varepsilon)^u) = \bigcup_{u' \leq u} I_{u'}$. For a given interval I_u and set $S \in \mathcal{F}_u$, we construct a table entry $T(u, S)$ with a $(1 + \mathcal{O}(\varepsilon))$-approximation to the optimal cost of a weight schedule of S subject to $C_j^w < (1+\varepsilon)^u$ for all $j \in S$.

Consider now $S \in \mathcal{F}_u$ and $S' \in \mathcal{F}_{u-1}$ with $S' \subseteq S$. Let $\mathcal{S}$ be a partial solution scheduling all jobs in S. Further assume that the set of jobs with completion weight in I_u is $S \setminus S'$. We define $\mathrm{APX}_u(S', S) = (1+\varepsilon)^u \sum_{j \in S \setminus S'} x_j^{\mathcal{S}}$, which is a $(1+\varepsilon)$-approximation of $\sum_{j \in S \setminus S'} x_j^{\mathcal{S}} C_j^w$, the partial cost associated with $S \setminus S'$. We remark that the values $\sum_{j \in S \setminus S'} x_j^{\mathcal{S}}$ and $\mathrm{APX}_u(S', S)$ do not depend on the whole schedule $\mathcal{S}$, but only on the total work volume of jobs in S' and S. Moreover, this value can be computed with two calls to the oracle,

$$\sum_{j \in S \setminus S'} x_j^{\mathcal{S}} = f\left(\sum_{j \in J \setminus S'} v_j\right) - f\left(\sum_{j \in J \setminus S} v_j\right).$$

We can compute $T(u, S)$ with the following formula,

$$T(u, S) = \min\{T(u-1, S') + \mathrm{APX}_u(S', S) : S' \in \mathcal{F}_{u-1}, S' \subseteq S\}.$$

The set $\mathcal{F}_u$ can be of exponential size, and thus also this dynamic programming table. In the following we show that there is a polynomial size set $\tilde{\mathcal{F}}_u$ that yields $(1+\varepsilon)$-approximate solutions. We remark that the set $\tilde{\mathcal{F}}_u$ will not depend on the speed of the machine. We only need to consider the information about the speed function for computing $\mathrm{APX}_u(S', S)$ while constructing the dynamic programming table.

3.2. Basic rounding and idle weight generation. In order to gain structure, we start by applying several modifications to the instance and optimal solution. Consider $0 < \varepsilon < 1/2$. We will apply two important procedures to modify weight schedules. They are used to create idle weight so as to apply Observation 2.1, and they only increase the total cost by a factor $1 + \mathcal{O}(\varepsilon)$. Similar techniques, applied in time space, were used by Afrati et al. [1] for problems on constant-speed machines.

1. *Weight stretch:* We multiply by $1+\varepsilon$ the completion weight of each job. This creates an idle weight interval of length εw_j before the starting weight of job j. This operation increases the cost by a $1+\varepsilon$ factor.
2. *Stretch intervals:* We delay the completion weight of each job j with $C_j^w \in I_u$ by $|I_u|$, so that C_j^w belongs to I_{u+1}. Then $|I_{u+1}| - |I_u| = \varepsilon^2(1+\varepsilon)^{u-1} = \varepsilon|I_{u+1}|/(1+\varepsilon)$ units of weight are left idle in I_{u+1} after the transformation,

unless there was only one job completely covering I_u. By moving jobs within I_{u+1}, we can assume that this idle weight is consecutive. This transformation increases the cost by at most a factor $(1+\varepsilon)^2 = 1 + \mathcal{O}(\varepsilon)$.

3.3. Light jobs. We structure an instance by classifying jobs by their size in weight space. This classification allows us to determine the schedule of part of the jobs greedily, which will help us to define compact sets $\tilde{\mathcal{F}}_u$ properly.

DEFINITION 3.1. *Given a schedule and a job j with starting weight $S_j^w \in I_u$, we say that j is* light for S_j^w *if $w_j \le \varepsilon^2 |I_u|$. A job that is not light is* heavy for S_j^w.

To simplify notation, we say that a job is light or heavy when the starting weight S_j^w is clear from the context.

Given a weight schedule for heavy jobs, we give a greedy algorithm for scheduling light jobs that increases the cost by a $1 + \mathcal{O}(\varepsilon)$ factor. Consider any weight schedule $\mathcal{S}$. First, remove all light jobs. Then we move jobs within each interval I_u, such that the idle weight in I_u is consecutive. Clearly, this can only increase the cost of the solution by a factor $1+\varepsilon$. Then, we apply a preemptive greedy algorithm to assign light jobs, namely, Smith's rule [26]. More precisely, for each idle weight w we process the job j that maximizes v_j/w_j among jobs that are not completely processed yet and $w_j \le \varepsilon^2 |I_u|$. (Here we give priority to jobs with smallest weight to work volume ratio, which is the opposite of the standard Smith's rule; intuitively, this is because in weight space jobs are scheduled in reversed order as in time space.) To remove preemptions, we apply the stretch interval subroutine,[1] creating an idle weight interval in I_u of length at least $\varepsilon|I_u|/(1+\varepsilon) \ge \varepsilon|I_u|/2 \ge \varepsilon^2|I_u|$ (since $\varepsilon \le 1/2$). This gives enough space in each interval I_u to completely process the (unique) preempted light job with starting weight in I_u. The algorithm returns this last schedule, called $\mathcal{S}'$. Summarizing, the algorithm is as follows.

Algorithm 3.1 Smith in Weight Space.

Input: A weight schedule $\mathcal{S}$.

1: Remove all light jobs in $\mathcal{S}$ and move the remaining jobs within each interval I_u, such that the idle weight in I_u is consecutive.
2: *Reverse Smith's rule*: For $u = 1, \ldots, \nu$ and each idle weight $w \in I_u$, process at w a job j maximizing v_j/w_j among all available jobs with $w_j \le \varepsilon^2|I_u|$.
3: Apply the stretch intervals subroutine.
4: For each u move the unique preempted light job with starting weight in I_u (if any) so that it is completely processed within I_u.
5: **return** Return the constructed schedule $\mathcal{S}'$.

We now show that the cost of the schedule $\mathcal{S}'$ returned by the algorithm is at most a factor $1 + \mathcal{O}(\varepsilon)$ larger than the cost of $\mathcal{S}$. To do so we need a few definitions.

DEFINITION 3.2. *Given a weight schedule $\mathcal{S}$, its* remaining volume function *is defined as*

$$V^{\mathcal{S}}(w) := \sum_{j : C_j^w \ge w} v_j.$$

Recall the definition of function $f(v)$ given by (2.1). It is easy to see—even from the 2D Gantt chart—that $\int_0^\infty f(V^{\mathcal{S}}(w))dw$ corresponds to the cost of the weight

[1] The stretch interval procedure also applies to preemptive settings by interpreting each piece of a job as an independent job.

schedule $\mathcal{S}$. Also, notice that $f(v)$ is nondecreasing, so that $V^{\mathcal{S}}(w) \leq V^{\mathcal{S}'}(w)$ for all $w \geq 0$ implies that the cost of $\mathcal{S}$ is at most the cost of $\mathcal{S}'$.

DEFINITION 3.3. *For a given w, let $I_j(w)$ be equal to 1 if the weight schedule processes j at weight w, and 0 otherwise. Then, $\chi_j(w) := (1/w_j)\int_w^\infty I_j(w')dw'$ corresponds to the fraction of job j processed after w. The* fractional remaining volume function *of a weight schedule $\mathcal{S}$ is defined as*

$$V_f^{\mathcal{S}}(w) := \sum_{j:j \text{ is light}} \chi_j(w) \cdot v_j + \sum_{j:j \text{ is heavy}, C_j^w \geq w} v_j \qquad \text{for all } w \geq 0.$$

Intuitively, this function is similar to the (nonfractional) remaining volume function with the difference that it treats light jobs as "liquid." Also, notice that $V_f^{\mathcal{S}}(w) \leq V^{\mathcal{S}}(w)$ for all $w \geq 0$.

LEMMA 3.4. *Let $\mathcal{S}$ be a weight schedule and $\mathcal{S}'$ be the output of Algorithm Smith in Weight Space on input $\mathcal{S}$. Then the cost of $\mathcal{S}'$ is at most a factor $1 + \mathcal{O}(\varepsilon)$ larger than the cost of $\mathcal{S}$.*

Proof. Let $\mathcal{S}_i$ be the schedule constructed after step i of the algorithm for each $i \in \{1, 2, 3, 4\}$. In particular, $\mathcal{S}_1$ schedules only heavy jobs and $\mathcal{S}_4 = \mathcal{S}'$. First we observe that for any given $w \geq 0$, $V_f^{\mathcal{S}_2}(w)$ is a lower bound on $V_f^{\hat{\mathcal{S}}}(w)$ for any schedule $\hat{\mathcal{S}}$ that coincides with $\mathcal{S}_2$ on the heavy jobs. This follows by a simple exchange argument, since the greedy Smith-type rule in step 2 chooses the job that packs as much volume as possible in the available weight among all light jobs. We conclude that $V_f^{\mathcal{S}_2}(w) \leq V_f^{\mathcal{S}}(w)$ for all w.

Observe that applying stretch intervals can delay any piece of a job by at most a factor $(1+\varepsilon)^2$. Therefore $V_f^{\mathcal{S}_3}(w) \leq V_f^{\mathcal{S}_2}((1+\varepsilon)^{-2}w)$. Also, in step 4 pieces of jobs are only moved backwards and thus $V_f^{\mathcal{S}_4} \leq V_f^{\mathcal{S}_3}$. Finally, we notice that each of the light jobs in $\mathcal{S}_4$ is processed completely within an interval I_u, and thus $V^{\mathcal{S}_4}(w) \leq V_f^{\mathcal{S}_4}((1+\varepsilon)^{-1}w)$.

Combining all of our observations we obtain that

$$\begin{aligned} V^{\mathcal{S}_4}((1+\varepsilon)^3 w) &\leq V_f^{\mathcal{S}_4}((1+\varepsilon)^2 w) \leq V_f^{\mathcal{S}_3}((1+\varepsilon)^2 w) \\ &\leq V_f^{\mathcal{S}_2}(w) \leq V_f^{\mathcal{S}}(w) \leq V^{\mathcal{S}}(w) \quad \text{for all } w \geq 0. \end{aligned}$$

Taking the function $f(\cdot)$ and integrating implies that

$$\int_0^\infty f(V^{\mathcal{S}_4}((1+\varepsilon)^3 w))dw \leq \int_0^\infty f(V^{\mathcal{S}}(w))dw.$$

Finally, the right-hand side of this inequality is the cost of $\mathcal{S}$, and a simple change of variables implies that the left-hand side is $(1+\varepsilon)^{-3}$ times the cost of $\mathcal{S}' = \mathcal{S}_4$. The lemma follows. ∎

The next corollary follows directly from our previous result.

COROLLARY 3.5. *At a loss of a factor $1 + \mathcal{O}(\varepsilon)$ in the objective function, we can assume the following. For a given interval I_u, consider any pair of jobs j, k whose weights are at most $\varepsilon^2|I_u|$. If both jobs are processed in I_u or later and $v_k/w_k \leq v_j/w_j$, then $C_j^w \leq C_k^w$.*

3.4. Localization. The objective of this section is to compute, for each job $j \in J$, two values r_j^w and d_j^w so that job j is scheduled completely within $[r_j^w, d_j^w)$ in some $(1+\mathcal{O}(\varepsilon))$-approximate weight schedule. We call r_j^w and d_j^w the *release weight* and *deadline weight* of job j, respectively. Crucially, we need that the length of the interval $[r_j^w, d_j^w)$ is not too large, namely, that $d_j^w \in \mathcal{O}(\text{poly}(1/\varepsilon) r_j^w)$. Such values can be obtained by using Corollary 3.5 and techniques from [1]. The release and deadline weights will be the key to finding compact sets $\tilde{\mathcal{F}}_u$ in the next subsection.

We start by rounding the weights of the jobs to the next integer power of $1+\varepsilon$, which increases the objective function by at most a factor $1+\varepsilon$. To define the release and deadline weights, we consider an initial value for r_j^w and then increase its value iteratively. We will restrict ourselves to values of r_j^w that are integer powers of $1+\varepsilon$. Consider an arbitrary weight schedule. Recall that for a job with completion weight C_j^w, the weight stretch subroutine (section 3.2) increases the completion weight $(1+\varepsilon)C_j^w$ and, hence, the starting weight to $S_j^w = \varepsilon C_j^w$. Applying the procedure twice we get a solution that satisfies $S_j^w \geq \varepsilon(1+\varepsilon)C_j^w \geq \varepsilon(1+\varepsilon)w_j$. Thus, we can safely define r_j^w as εw_j rounded up to an integer power of $1+\varepsilon$.

We now show how to adapt techniques from [1] used for time schedules. Let J_u be the set of all jobs with r_j^w equal to $(1+\varepsilon)^{u-1}$. We partition J_u into light and heavy jobs, depending on if their weight is smaller or larger than $\varepsilon^2|I_u|$. Note that a heavy job in J_u can have weights w with $\varepsilon^2|I_u| < w \leq 1/\varepsilon(1+\varepsilon)^{u-1}$, where the last inequality follows since $r_j^w \geq \varepsilon w_j$. Therefore, since we are assuming that the weights of jobs are integer powers of $1+\varepsilon$, for a fixed u we only need to consider heavy jobs with weights

$$w \in \Omega_u := \left\{ (1+\varepsilon)^i : \varepsilon^2|I_u| < (1+\varepsilon)^i \leq \frac{(1+\varepsilon)^{u-1}}{\varepsilon}, \text{ where } i \in \mathbb{Z} \right\}.$$

Crucially, note that $|\Omega_u| \in \mathcal{O}(\log_{1+\varepsilon} 1/\varepsilon) \subseteq \mathcal{O}(1/\varepsilon \cdot \log 1/\varepsilon)$. Based on this we give the following decomposition of the set of jobs with a given release weight.

DEFINITION 3.6. *Given release weights for each job, we define for each u the set $J_u = \{j : r_j^w = (1+\varepsilon)^{u-1}\}$. Additionally, we decompose J_u into a set of light jobs $L_u := \{j \in J_u : w_j \leq \varepsilon^2|I_u|\}$, and sets $H_{u,w} = \{j \in J_u : w_j = w\}$ of heavy jobs of weight w for each $w \in \Omega_u$.*

Now we consider all jobs in L_u. If $w(L_u)$ is larger than $(1+\varepsilon^2)|I_u|$ then some jobs in L_u will have to start in I_{u+1} or later. By Corollary 3.5 we can greedily choose the set of possible jobs with starting weight in I_u, and increase the release weight of the rest. Similarly, since the weight of each job in $H_{u,w}$ is the same, we can always give priority to jobs with the largest work volume. With this idea we can show the following lemma.

LEMMA 3.7. *We can compute in polynomial time release weights r_j^w for each job j such that there exists a $(1+\mathcal{O}(\varepsilon))$-approximate weight schedule respecting the release weights and for any interval I_u we have that $w(J_u) \in \mathcal{O}(1/\varepsilon^3 \cdot \log 1/\varepsilon \cdot |I_u|)$. And this weight schedule satisfies the property of Corollary* 3.5.

Proof. Initialize r_j^w, as εw_j rounded up to an integer power of $(1+\varepsilon)$ and let J_u, L_u, and $H_{u,w}$ be defined as above. By Corollary 3.5 we know that within an interval I_u we can order light jobs and process a job with largest v_j/w_j ratio. Thus, if the total weight of jobs in L_u is larger than $(1+\varepsilon^2)|I_u|$ we increase the release weight of a job $j^* \in \arg\min_{j \in L_u} v_j/w_j$ to $(1+\varepsilon)^u$. Note that after doing this j^* does not belong to L_u anymore. We iterate this procedure until $w(L_u) \leq (1+\varepsilon^2)|I_u|$.

We do a similar technique for jobs in $H_{u,w}$. If $w(H_{u,w}) > |I_u| + w$ and $|H_{u,w}|$ contains more than one job, then we can delay the release weight of a job $j^* \in H_{u,w}$ with smallest v_j. This follows by a simple interchange argument, since if there are two jobs with the same weight then the one with smallest work has smaller (larger) completion time (weight) in an optimal solution. After modifying the release date of j^* this job does not belong to $H_{u,w}$ anymore.

This way we obtain a set $H_{u,w}$ with

$$w(H_{u,w}) \leq |I_u| + w \leq |I_u| + \frac{1}{\varepsilon}(1+\varepsilon)^{u-1} \in \mathcal{O}(1/\varepsilon^2) \cdot |I_u|.$$

We execute the two procedures described above for each $u = 0, \ldots, \nu$, where $\nu = \lceil \log_{1+\varepsilon} \sum_{j \in J} w_j \rceil$ until the following property holds: for all $u \in \{0, \ldots, \nu\}$ and $w \in \Omega_u$ we have that $w(L_u) \leq (1+\varepsilon^2)|I_u|$ and $w(H_{u,w}) \in \mathcal{O}(1/\varepsilon^2) \cdot |I_u|$. The result follows since $|\Omega_u| \in \mathcal{O}(1/\varepsilon \cdot \log 1/\varepsilon)$. ∎

We use the previous lemma to define the deadline weights by using the following idea. For s large enough (but constant), stretch intervals creates enough idle weight in I_{u+s} to fit all jobs released at $(1+\varepsilon)^u$ that have not yet finished by $(1+\varepsilon)^{u+s+1}$. This allows us to apply Observation 2.1.

LEMMA 3.8. *We can compute in polynomial time values r_j^w and d_j^w for each $j \in J$ such that the following properties hold:*

(i) *there exists a $(1+\mathcal{O}(\varepsilon))$-approximate weight schedule that runs each job j within $[r_j^w, d_j^w)$;*
(ii) *there exists a constant $s \in \mathcal{O}(\log(1/\varepsilon)/\varepsilon)$ such that $d_j^w \leq r_j^w \cdot (1+\varepsilon)^s$;*
(iii) *r_j^w and d_j^w are integer powers of $(1+\varepsilon)$;*
(iv) *within each, L_u jobs are processed following the Reverse Smith's rule; and*
(v) *the values r_j^w and d_j^w are independent of the speed of the machine.*

Proof. Consider the release weights given by the previous lemma and consider the associated sets J_u for each u. Then, since $w(J_u) \in \mathcal{O}(1/\varepsilon^3 \cdot \log 1/\varepsilon \cdot |I_u|)$, there exists an integer $s \in \mathcal{O}(\log_{1+\varepsilon}(1/\varepsilon^4 \cdot \log 1/\varepsilon)) \subseteq \mathcal{O}(\log(1/\varepsilon)/\varepsilon)$ such that $w(J_u) \leq \varepsilon |I_{u+s-1}|/(1+\varepsilon)$.

Consider now the $(1+\mathcal{O}(\varepsilon))$-approximate solution obtained from the previous lemma (which, by construction, also satisfies the property of Corollary 3.5). By construction of r_j^w, we can assume that the starting weight of j in this schedule is at least r_j^w. Now we apply stretch intervals. This creates $\varepsilon|I_{u+s-1}|/(1+\varepsilon)$ idle weight in interval I_{u+s-1}, unless there was one job completely covering I_{u+s-1}. If that is not the case, then we can move all jobs in J_u with starting weight in I_{u+s} or larger to be completely processed inside I_{u+s-1}. By Observation 2.1, doing this can only increase the objective function by a $1+\mathcal{O}(\varepsilon)$ factor. Similarly, if there was a job k completely covering I_{u+s-1}, then the idle weight that I_{u+s-1} should have contained can be considered to be just before the starting weight of k. In this case we can move all jobs in J_u that were being processed after I_{u+s-1} to just before S_k^w.

In either case we constructed a solution where each job in J_u is completely processed in $[(1+\varepsilon)^{u-1}, (1+\varepsilon)^{u+s-1})$. Properties (i)–(iii) in the lemma follow by defining $d_j^w = (1+\varepsilon)^{u+s-1} = r_j^w(1+\varepsilon)^s$ for each job $j \in J_u$. Also property (iv) follows since our original schedule satisfies the property of Corollary 3.5 and our modification does not change the relative order of jobs in J_u. Finally (v) follows since while defining r_j^w and d_j^w we never used the speed of the machine. ∎

3.5. Compact search space. Given the job classification and localization in the previous subsections, we are now ready to reduce the running time of the DP in section 3.1 to polynomial time. To that end, recall the definition of families of job sets $\mathcal{F}_u$. We will define a constant size version of it, $\tilde{\mathcal{F}}_u$. Instead of describing a set $S \in \tilde{\mathcal{F}}_u$, we describe $R = J \setminus S$, that is, the jobs with completion weights in I_{u+1} or later. That is, we define a set $\mathcal{D}_u$ that will contain the complements of sets in $\tilde{\mathcal{F}}_u$. In order to define $\mathcal{D}_u$ we use the release and deadline weights given by Lemma 3.8. If $R \in \mathcal{D}_u$, then R must contain all jobs $j \in \overline{R} := \{k \in J : r_k^w \geq (1+\varepsilon)^u\}$.

Observation 3.9. Each set $R \in \mathcal{D}_u$ is of the form $R' \cup \overline{R}$, where every job $j \in R'$ has $r_j^w \leq (1+\varepsilon)^{u-1}$.

Thus we only need to describe all possibilities for R'. For a job $j \in R'$ we can assume that $d_j^w \geq (1+\varepsilon)^{u+1}$. Therefore, by Lemma 3.8, we have that $r_j^w \geq (1+\varepsilon)^{u+1-s}$, where $s \in \mathcal{O}(\log(1/\varepsilon)/\varepsilon)$.

Observation 3.10. Each set $R = R' \cup \overline{R} \in \mathcal{D}_u$ is of the form $\left(\bigcup_{v=u+2-s}^{u} R'_v\right) \cup \overline{R}$, where $R'_v := \{j \in R' : r_j^w = (1+\varepsilon)^{v-1}\}$.

Then, we aim to find a collection of subsets that can play the role of R'_v. If the size of this collection is at most a constant number k, we could conclude that $|\mathcal{D}_u| \leq k^{s-1} = k^{\mathcal{O}(\log(1/\varepsilon)/\varepsilon)}$.

In order to do so, recall that J_v denotes the set of all jobs with release weights equal to $(1+\varepsilon)^{v-1}$, and that we can write $J_v = L_v \cup (\bigcup_w H_{v,w})$, where $w \in \Omega_v$ and $|\Omega_v| \in \mathcal{O}(\log_{1+\varepsilon} 1/\varepsilon)$. Thus, defining $R'_{v,w} := R'_v \cap H_{v,w}$ we can further decompose R'_v as $(R'_v \cap L_v) \cup (\bigcup_w R'_{v,w})$. Now notice that $R'_{v,w}$ is a subset of $H_{v,w}$ which, as seen in the proof of the next observation, has a very simple structure.

Observation 3.11. Without loss of generality, we can restrict ourselves to consider sets $R'_{v,w}$ among $\mathcal{O}(1/\varepsilon^2)$ distinct options.

Proof. Let $w \in \Omega_v$. Each job in $H_{v,w}$ has weight w and, as seen in the proof of Lemma 3.7, we have that $w(H_{v,w}) \leq |I_v| + w$. Thus $H_{v,w}$ contains at most $1 + |I_v|/w$ many jobs. Since by the definition of $H_{v,w}$ we have that $w \geq \varepsilon^2 |I_v|$, we obtain that $|H_{v,w}| \in \mathcal{O}(1/\varepsilon^2)$. Moreover, all jobs in $H_{v,w}$ has the same weight w and the same release weight. Therefore, we know that these jobs are ordered by their work volume in an optimal solution. Thus, we can restrict ourselves to sets $R'_{v,w}$ that respect this order. The observation follows since there are at most $|H_{v,w}| + 1 \in \mathcal{O}(1/\varepsilon^2)$ many sets that respect this order. ∎

Given v, the index w ranges over $|\Omega_v| \in \mathcal{O}(\log(1/\varepsilon)/\varepsilon)$ many values. Thus the following holds.

Observation 3.12. For each value v, the set $\bigcup_w R'_{v,w}$ can be chosen over $(1/\varepsilon^2)^{\mathcal{O}(\log(1/\varepsilon)/\varepsilon)} = 2^{\mathcal{O}(\log(1/\varepsilon)^2/\varepsilon)}$ many alternatives.

We use a similar argument for $R'_v \cap L_v$. Indeed, as seen in the proof of Lemma 3.7, $w(L_v) \leq (1+\varepsilon^2)|I_v|$ and jobs in L_v will be processed as light jobs (by Lemma 3.8). We now show that we can group light jobs together in order to diminish the possibilities for L_v. This is done as follows. Set jobs in L_v in a list ordered by the Reverse Smith's rule, as in Algorithm Smith in Weight Space. Then we greedily find groups of jobs in L_v by going through the list of jobs from left to right such that each group has its total weight in $[\varepsilon^2|I_v|, 2\varepsilon^2|I_v|]$ (except from the last group that might have smaller

total weight). Recalling that $w(L_v) \in (1+\varepsilon^2)|I_v|$, we obtain that this procedure creates at most $\mathcal{O}(1/\varepsilon^2)$ groups. Let $L_{v,i}$ be the ith of these groups.

LEMMA 3.13. *There exists a $(1+\mathcal{O}(\varepsilon))$-approximate weight schedule such that*
(i) *it satisfies the release and deadline weights of Lemma* 3.8*;*
(ii) *in each group $L_{v,i}$ all jobs are processed consecutively; and*
(iii) *within each set L_v jobs are processed following the Reverse Smith's rule.*

Proof. Consider the schedule given by Lemma 3.8, and thus within each J_v jobs follow the Reverse Smith's rule. Let us fix an interval $I_{v'}$. Within this interval, the schedule can only process jobs in J_v with $v \le v'$. Within a given J_v we follow the Reverse Smith's rule, thus there is at most two sets $L_{v,i}$ that are partially processed in $I_{v'}$. They require at most $4\varepsilon^2|I_v|$ extra weight within $I_{v'}$ in order to be completely processed in $I_{v'}$. Summing over all $v \le v'$, we obtain that in total we require

$$4\varepsilon^2 \sum_{v \le v'} |I_v| = 4\varepsilon^3 \sum_{v \le v'} (1+\varepsilon)^v \in \mathcal{O}(\varepsilon |I_{v'}|)$$

extra space in $I_{v'}$. The result follows since we can create enough idle time within $I_{v'}$ by applying $\mathcal{O}(1)$ times the procedure stretch intervals. We remark that the procedure described works *simultaneously* for all intervals $I_{v'}$. ∎

With this lemma, we can find a compact description to $R'_v \cap L_v$. Indeed, to specify $R'_v \cap L_v$, i.e., the jobs in L_v that are processed in I_{u+1} or later, we just need to determine the index i such that jobs in $L_{v,k}$ with $k \ge i$ are in R'_v and jobs in $L_{v,k}$ with $k < i$ are not in R'_v. Since i ranges over $\mathcal{O}(1/\varepsilon^2)$ many options, we obtain the following.

Observation 3.14. The set $R'_v \cap L_v$ can be chosen over $\mathcal{O}(1/\varepsilon^2)$ different options.

Combining this last observation and Observation 3.12, we obtain that R'_v can take at most $k \le 2^{\mathcal{O}(\log^2(1/\varepsilon)/\varepsilon)}$ many different options. By Observation 3.10, we conclude that R' belongs to a set of size at most $k^{s-1} \le 2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)}$. With this and Observation 3.9, we can define $\mathcal{D}_u$ as having size at most $2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)}$. Finally, we define $\tilde{\mathcal{F}}_u = \{R : R^c \in \mathcal{D}_u\}$ for each u.

LEMMA 3.15. *We can construct in polynomial time a set $\tilde{\mathcal{F}}_u$, for each u, that satisfies the following properties:*
(i) *there exists a $(1+\mathcal{O}(\varepsilon))$-approximate weight schedule in which the set of jobs with completion weight at most $(1+\varepsilon)^u$ belongs to $\tilde{\mathcal{F}}_u$ for each interval u;*
(ii) *the set $\tilde{\mathcal{F}}_u$ has cardinality at most $2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)}$; and*
(iii) *the set $\tilde{\mathcal{F}}_u$ is completely independent of the speed of the machine.*

With this lemma and the discussion at the beginning of this section we obtain a PTAS, which is best possible from an approximation point of view, since the problem is known to be strongly NP-hard [16].

THEOREM 3.16. *There exists an efficient PTAS for minimizing the weighted sum of completion times on a machine with given varying speed.*

Proof. It remains to argue that the described algorithm is efficient. It is easy to see that the time for creating sets $\tilde{\mathcal{F}}_u$ is dominated by the time needed to solve the DP. Moreover, the number of entries of the table is $2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)} \cdot \log(\sum_j w_j)$, and

the time needed to fill each entry is $2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)} \cdot n$. Therefore the running time[2] is

$$2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)} \cdot \log\left(\sum_j w_j\right) \cdot 2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)} \cdot n = 2^{\mathcal{O}(\log^3(1/\varepsilon)/\varepsilon^2)} \cdot \log\left(\sum_j w_j\right) \cdot n.$$

∎

4. Speed-scaling for continuous speeds. We now consider the dynamic speed-scaling setting in which the machine can run at any nonnegative speed s, and it is part of the scheduling problem to decide upon the speed. Running the machine at speed s implies a power consumption rate of $P(s) = s^\alpha$ for some constant $\alpha \geq 1$. The total energy consumed is the power consumption integrated over time. We study the problem of minimizing $\sum_j w_j C_j$ for a given amount of available energy E.

In this setting, we may assume that an optimal solution executes each job at a uniform speed. This follows directly from the convexity of the power function [31]. Let s_j be the speed at which job j is running. Then j's power consumption is $p_j = s_j^\alpha$, and its execution time is $x_j = v_j/s_j = v_j/p_j^{1/\alpha}$. The energy that is required for processing j is

$$E_j = p_j \cdot x_j = p_j \cdot v_j/s_j = s_j^{\alpha-1} \cdot v_j = v_j^\alpha/x_j^{\alpha-1}.$$

Let π be a sequence of jobs in a schedule, where $\pi(j)$ is the index of the jth job in the sequence. We can compute the optimal energy assignment for all jobs in a given sequence π using a total amount of energy E by a convex program. We rewrite the objective function as

$$\sum_{j=1}^n w_j C_j = \sum_{j=1}^n w_{\pi(j)} \sum_{k=1}^j x_{\pi(k)} = \sum_{j=1}^n x_{\pi(j)} \sum_{k=j}^n w_{\pi(k)}$$

and define $W^\pi_{\pi(j)} = \sum_{k=j}^n w_{\pi(k)}$. Note that $x_j = \left(v_j^\alpha/E_j\right)^{1/(\alpha-1)}$, and that W_j^π is the total remaining weight just before j is completed in any schedule concordant with π. Then the problem can be formulated as

$$\min\left\{\sum_{j=1}^n W_j^\pi \cdot \left(\frac{v_j^\alpha}{E_j}\right)^{1/(\alpha-1)} : \sum_{j=1}^n E_j \leq E, \text{ and } E_j \geq 0 \quad \forall j\right\}. \tag{4.1}$$

This program has linear constraints and a convex objective function. Such programs can be solved in polynomial time up to an arbitrary precision [23] with the ellipsoid method. However, the well-known Karush–Kuhn–Tucker (KKT) [7] conditions yield an explicit formula for the optimal energy assignment.

The problem in (4.1) is clearly feasible, for example, choose $E_j = 0$ for each $j \in \{1, \ldots, n\}$. Moreover, an optimal solution satisfies the first constraint with equality. Indeed, we allow arbitrary nonnegative speeds and thus arbitrary energy assignments, and the smallest increase in the assigned energy decreases the total cost. For the same reason and with a positive energy budget, an optimal solution never assigns zero energy to any job; hence, $E_j > 0$ for each job j. With these observations the KKT conditions reduce to the following.

[2]We remark that in this expression we consider arithmetic operations to take time $\mathcal{O}(1)$, and thus we neglect the size of the numbers output by the oracle. However considering this effect can only add a polynomial term on the maximum encoding size of a number output by the oracle. Recall that we allow efficient algorithms to be of that form.

LEMMA 4.1 (KKT conditions). *A vector $(E_1, \dots, E_n)$ is an optimal solution to the convex program in* (4.1) *if and only if*

(a) *$(E_1, \dots, E_n)$ is feasible and satisfies $\sum_{j=1}^{n} E_j = E$ and $E_j > 0$ for all j, and*

(b) *there exists a parameter $\lambda \geq 0$ such that $\nabla g(E_1, \dots, E_n) + \lambda \cdot \mathbf{1} = 0$,*

where $\mathbf{1}$ denotes a vector with ones in each coordinate and g is the objective function in (4.1).

THEOREM 4.2. *The optimal solution to* (4.1) *is given by*

$$E_j = v_j \cdot \left(W_j^{\pi}\right)^{(\alpha-1)/\alpha} \cdot \frac{E}{\gamma_\pi}, \text{ where } \gamma_\pi = \sum_{j=1}^{n} v_j \cdot \left(W_j^{\pi}\right)^{(\alpha-1)/\alpha}.$$

Proof. Since we fix a permutation π, we omit the extra script in W_j^{π} and γ_π during the rest of this proof. Let $(E_1, \dots, E_n)$ be an optimal solution to (4.1). By Lemma 4.1(b), there is a $\lambda \geq 0$ such that for every job $j \in \{1, \dots, n\}$ it holds that

$$W_j \cdot v_j^{\alpha/(\alpha-1)} \cdot \frac{-1}{\alpha - 1} \cdot E_j^{-\alpha/(\alpha-1)} + \lambda = 0\,,$$

which is equivalent to

$$E_j = v_j \cdot W_j^{(\alpha-1)/\alpha} \cdot \left(\frac{1}{(\alpha-1)\lambda}\right)^{(\alpha-1)/\alpha}. \tag{4.2}$$

To determine the Lagrange multiplier λ we use Lemma 4.1(a),

$$E \;=\; \sum_{j=1}^{n} E_j \;=\; \sum_{j=1}^{n} v_j \cdot W_j^{(\alpha-1)/\alpha} \cdot \left(\frac{1}{(\alpha-1)\lambda}\right)^{(\alpha-1)/\alpha} \;=\; \gamma \cdot \left(\frac{1}{(\alpha-1)\lambda}\right)^{(\alpha-1)/\alpha}.$$

Then, we can express the values E_j in (4.2) independently of λ and conclude that $E_j = E \cdot v_j \cdot W_j^{\frac{\alpha-1}{\alpha}}/\gamma$. ∎

Using this optimal energy assignment (Theorem 4.2), the scheduling problem at hand reduces to finding the permutation π that minimizes

$$\sum_{j=1}^{n} w_j C_j(E) = \sum_{j=1}^{n} W_j^{\pi} \cdot \left(\frac{v_j^{\alpha}}{E_j}\right)^{\frac{1}{\alpha-1}} = \frac{1}{E^{\frac{1}{\alpha-1}}} \cdot \left(\sum_{j=1}^{n} v_j \cdot \left(W_j^{\pi}\right)^{\frac{\alpha-1}{\alpha}}\right)^{\frac{\alpha}{\alpha-1}}, \tag{4.3}$$

where the last equation comes from the definition of γ_π (see Theorem 4.2) and standard transformations. Interestingly, the optimal job sequence is independent of the energy distribution and, furthermore, it is independent of the overall energy budget. In other words, one scheduling sequence is universally optimal for all energy budgets. As we will see this sequence is obtained by solving *in weight space* a (standard) scheduling problem with a cost function that depends on the power function. A similar observation was independently made by Vásquez [29].

THEOREM 4.3. *Given a power function $P(s) = s^{\alpha}$, there is a universal sequence that minimizes $\sum_j w_j C_j$ for any energy budget. The sequence is given by reversing an optimal solution of the scheduling problem $1|\,|\sum w_j C_j^{(\alpha-1)/\alpha}$ (on a single machine of unit speed).*

Proof. Equation (4.3) implies that the optimal job sequence is independent of the available energy budget E since it only plays a role in the factor outside the sum, which is independent of the permutation. Since the exponent $\alpha/(\alpha-1)$ is constant, the problem of finding the optimal sequence under an optimal energy distribution reduces to finding the sequence that minimizes

$$\sum_{j=1}^{n} v_j \cdot \left(W_j^{\pi}\right)^{(\alpha-1)/\alpha}.$$

Now recall the reinterpretation that the 2D Gantt chart view offers (see section 2). Then W_j^{π} is the completion weight of job j in a schedule that follows sequence π in time space (and the reverse order in weight space). We conclude that this problem is equivalent to the scheduling problem in *weight space* with *varying speed on the weight axis or general cost function in the weight space.* This problem can be directly translated into minimizing the total weighted completion time on a machine with varying speed (or the desired form with a generalized cost function) by reinterpreting weight space as time space. We simply define a new problem in time space with processing times $v'_j = w_j$ and weight $w'_j = v_j$, where the objective is to find a permutation of jobs minimizing $\sum_{j=1}^{n} w'_{\pi(j)} \cdot f(\sum_{k=1}^{j} v'_{\pi(k)})$ for $f : x \to x^{(\alpha-1)/\alpha}$. This is a problem of the desired type. By section 2 it is easy to see that a solution π' to the new problem in time space has a corresponding solution π in the weight space with same total cost; π is the reverse of π'. ∎

Thus, the scheduling part of the speed-scaling scheduling problem reduces to a problem which can be solved by our PTAS from section 3. Since the cost function $f(x) = x^{(\alpha-1)/\alpha}$ is concave for $\alpha > 1$, the specialized PTAS in [27] also solves it. Combining Theorems 4.2 and 4.3 gives the main result.

THEOREM 4.4. *Let $\alpha \geq 1$ be a (constant) rational number. There is a PTAS for the continuous speed-scaling and scheduling problem with a given energy budget E for continuous speed and power function $P(s) = s^{\alpha}$. Indexing jobs in this order, the $(1+\varepsilon)$-approximate Pareto curve describing the approximate scheduling cost as a function of the available energy is given by the right-hand side of* (4.3).

Proof. The previous theorem argues that our energy problem is equivalent to $1|\,|\sum w_j C_j^{(\alpha-1)/\alpha}$ in terms of optimal solutions. However, approximation factors are not exactly preserved: as can be seen from (4.3), a solution with cost Z for $1|\,|\sum w_j C_j^{(\alpha-1)/\alpha}$ corresponds to a solution of cost $Z^{\frac{\alpha}{\alpha-1}}$ for the speed-scaling problem. Hence, a β-approximation algorithm for the static-speed problem yields an approximation factor of $\beta^{\alpha/(\alpha-1)}$ for the dynamic-speed problem. Since $\alpha \geq 1$ is a constant, taking $\beta = (1+\varepsilon)$ yields an approximation factor of $(1+\varepsilon)^{\alpha/(\alpha-1)} = 1+\mathcal{O}(\varepsilon)$ for the speed-scaling problem (for small enough $\varepsilon > 0$). Therefore it suffices to give a PTAS for $1|\,|\sum w_j C_j^{(\alpha-1)/\alpha}$.

To apply Theorem 3.16 it suffices to specify the oracle function f. In our case $f(x) = x^{(\alpha-1)/\alpha}$ might yield irrational numbers. However, since we aim for a PTAS it suffices to define a polynomial-time oracle $\tilde{f}$ that approximates f within a $1+\varepsilon$ factor. This can be done with standard techniques from numerical analysis, e.g., Newton's method [28]. ∎

5. Speed-scaling for discrete speeds. In this section we consider a more realistic setting, where the machine speed can be chosen from a set of κ different speeds $s_1 > \cdots > s_\kappa > 0$. We also allow the machine to be run at zero speed,

which we assume to induce zero power consumption. For this problem we resolve the complexity status and show that it is NP-hard even when $\kappa = 2$. For arbitrarily many speed states we give a PTAS, and if κ is constant an FPTAS.

5.1. A PTAS for discrete speeds. To derive our algorithm, we adapt the PTAS for scheduling on a machine with given varying speed (section 3) and incorporate the allocation of energy. Fortunately, many of the techniques to derive that PTAS, in particular the computation of sets $\tilde{\mathcal{F}}_u$, are independent of the speed of the machine. Thus we can use them without modifications.

Consider the power function $P(s)$ to be an arbitrary computable function. We adopt the same definitions of weight intervals I_u and sets $\mathcal{F}_u$ as in section 3. For a subset of jobs $S \in \mathcal{F}_u$ and a value $z \geq 0$, let $E[u, S, z]$ be the minimum total energy necessary for scheduling S such that all completion weights are in interval I_u or before and the scheduling cost is at most z, i.e., $\sum_{j \in S} x_j \cdot C_j^w \leq z$, where x_j is the execution time under some feasible speed assignment. The recursive definition of a state is as follows:

$$E(u, S, z) = \min\{E(u-1, S', z') + \mathrm{APX}_u(S \setminus S', z - z') : S' \in \mathcal{F}_{u-1}, S' \subseteq S\}.$$

Here $\mathrm{APX}_u(S \setminus S', z - z')$ is the minimum energy necessary for scheduling all jobs $j \in S \setminus S'$ with $C_j^w \in I_u$, such that their partial (rounded) cost $\sum_{j \in S \setminus S'} x_j (1+\varepsilon)^u$ is at most $z - z'$.

LEMMA 5.1. *The value $APX_u(S \setminus S', z - z')$ can be computed in polynomial time.*

Proof. We set a linear program (LP) computing $\mathrm{APX}_u(S \setminus S', z - z')$. Let the solution variable $\ell_i \geq 0$, $i \in \{1, \ldots, \kappa\}$, denote the length of the time interval in which the machine is running at speed s_i. Consider the following LP,

$$\min \sum_{i=1}^{\kappa} \ell_i \cdot P(s_i),$$

$$\sum_{i=1}^{\kappa} \ell_i \cdot s_i = \sum_{j \in S \setminus S'} v_j, \tag{5.1}$$

$$\sum_{i=1}^{\kappa} \ell_i \cdot (1+\varepsilon)^u \leq z - z', \tag{5.2}$$

$$\ell_i \geq 0.$$

Here (5.1) guarantees that the total processing volume $v(S' \setminus S)$ can be completed, and (5.2) that the total scheduling cost does not exceed $z - z'$. ∎

We let the DP fill the table for $u \in \{0, \ldots, \nu\}$ with $\nu = \lceil \log_{1+\varepsilon} \sum_{j \in J} w_j \rceil$ and $z \in [1, z_{\mathrm{UB}}]$ for some upper bound such as $z_{\mathrm{UB}} = \sum_{j \in J} w_j \sum_{k=1}^{j} v_j / s_\kappa$. Then among all end states $[\nu, J, \cdot\,]$ with value at most the energy budget E we choose the one with minimum cost z. Then we obtain the corresponding $(1+\varepsilon)$-approximate solution for energy E by backtracking.

This DP has an exponential number of entries. However, we can apply results from section 3 and standard rounding techniques to reduce the running time.

THEOREM 5.2. *There is an efficient PTAS for minimizing the total scheduling cost for speed-scaling with a given energy budget.*

Proof. The DP computes a $(1+\varepsilon)$-approximate solution in exponential time. In Lemma 3.15, we showed how to reduce the exponential number of subsets in $\mathcal{F}_u$ to a polynomial number at the cost of a factor $1+\mathcal{O}(\varepsilon)$ in the total scheduling cost. Recall that the sets $\tilde{\mathcal{F}}_u$ given by that lemma are independent of the speed of the machine. Therefore we can use these sets directly in our setting.

It remains to reduce the number of possible values of cost $z \in [0, z_{\mathrm{UB}}]$. At the cost of a factor $1+\varepsilon$, we may round up in each state the scheduling cost to the next integer power of $1+\delta$ with $\delta = (1+\varepsilon)^{1/\nu} - 1$. In each state transition of the DP, we lose up to a factor $1+\delta$ in the scheduling cost, which amounts to at most a factor $(1+\delta)^{\nu} = 1+\varepsilon$ under ν state transitions. When restricting to powers of $1+\delta$, then the number of different values in $z \in [0, z_{\mathrm{UB}}]$ is bounded by $\mathcal{O}(\log_{1+\delta} z_{\mathrm{UB}}) = \mathcal{O}(\nu \cdot \log z_{\mathrm{UB}}/\varepsilon)$. Thus, the number of states in the table is polynomial. We conclude that the algorithm runs in polynomial time. ∎

5.2. Speed-scaling with discrete speeds is NP-hard. We show that speed-scaling for discrete speeds is NP-hard. We provide a reduction based on the problem of minimizing the total weighted tardiness of jobs with a common due date, $1|d_j = d|\sum w_j T_j$, which is known to be NP-hard [32]. Here, $T_j = \max\{C_j - d, 0\}$ denotes the tardiness of job j. We use the following generalization of this result for our reduction.

LEMMA 5.3. *The problem of minimizing $\sum w_j f(C_j)$ on a single machine of unit speed is NP-hard even when f is increasing, convex, and piecewise linear with only one breakpoint.*

Proof. Let $\varepsilon \geq 0$ and define the cost function

$$f_\varepsilon(x) = \begin{cases} \varepsilon \cdot x & \text{if } 0 \leq x < d, \\ x - d + \varepsilon d & \text{if } d \leq x. \end{cases}$$

Note that $T_j = f_0(C_j)$ is the tardiness of job j. Now we show that, for $\varepsilon > 0$ small enough, minimizing $\sum_j w_j T_j$ is equivalent to minimizing $\sum_j w_j f_\varepsilon(C_j)$.

Let $k \in \mathbb{N}$, and assume that w_j, p_j, and d are natural numbers for all j. It is known that the problem of deciding whether there exists a schedule with $\sum_j w_j T_j \leq k$ is NP-hard [32]. Now notice that

$$\begin{aligned} \sum_j w_j f_\varepsilon(C_j) &= \sum_{j:C_j<d} w_j \varepsilon C_j + \sum_{j:C_j \geq d} (C_j - d + \varepsilon d) w_j \\ &= \varepsilon \cdot \left(\sum_{j:C_j<d} w_j C_j + \sum_{j:C_j \geq d} d w_j \right) + \sum_j w_j f_0(C_j). \end{aligned}$$

Defining $\varepsilon = 1/(d\sum_j w_j) \leq 1$ (which can be described with polynomially many bits) we obtain that

$$\begin{aligned} 0 \leq \sum_j w_j f_\varepsilon(C_j) - \sum_j w_j f_0(C_j) &= \varepsilon \cdot \left(\sum_{j:C_j<d} w_j C_j + \sum_{j:C_j \geq d} d w_j \right) \\ &< \varepsilon d \sum_j w_j \leq 1. \end{aligned}$$

Therefore $\sum_j w_j f_0(C_j) \leq k$ if and only if $\sum_j w_j f_\varepsilon(C_j) \leq k+1$. We conclude that minimizing $\sum_j w_j f_\varepsilon(C_j)$ is NP-hard, where $\varepsilon \leq 1$ is considered as part of the input. ∎

Now we can prove the main result.

THEOREM 5.4. *The problem of minimizing $\sum_j w_j C_j$ on a single machine for discrete speeds is NP-hard, even if the number of available power levels is* 2.

Proof. The problem with $k > 2$ speed states can be reduced to the case with 2 speed states, by adding dummy states of arbitrarily slow speed. Therefore, we prove hardness of the case of two speeds $s_1 > s_2$.

Consider a scheduling instance on a unit-speed processor with the objective of minimizing $\sum_j w_j f_\varepsilon(C_j)$, where f_ε is defined in the proof of the previous lemma. We define an equivalent scheduling instance for minimizing $\sum_j w_j C_j$ on a machine with two possible speed states. In the new instance, the job set is the same and the values w_j and v_j for each job j are also preserved. Let $s_1 = 1/\varepsilon$ and $s_2 = 1$. The total energy budget is $E = V + d(1/\varepsilon^{\alpha-1} - 1)$, where V denotes the total work volume, $\sum_j v_j$. A simple interchange argument shows that in an optimal solution the machine runs at decreasing speeds. The time point when the speed changes is uniquely defined by the energy budget and the total work volume. In this case, the machine runs at speed s_1 until $\tau = \varepsilon d$ and then it runs at speed s_2. Also, the total work volume finished by τ is $\tau \cdot s_1 = d$.

Consider now a schedule without idle time on a machine with the speed profile just described. Assume that by relabeling the jobs the completion times satisfy that $C_1 < C_2 < \cdots < C_n$. Consider scheduling the jobs in a unit speed machine using the same permutation of jobs. In this new schedule the completion times are $C'_j = \sum_{k \le j} v_k$ for all j. If it easy to check that $f_\varepsilon(C'_j) = C_j$. We conclude that the problem of minimizing $\sum_j w_j f_\varepsilon(C'_j)$ is equivalent to minimizing $\sum_j w_j C_j$ on a machine that has speed $1/\varepsilon$ in the interval $[0, \varepsilon d]$ and speed 1 afterwards until all jobs are done. By Theorem 5.3 both problems are NP-hard, which concludes the proof. ∎

5.3. FPTAS for constantly many discrete speed-states. Consider the setting where the number of different (nonzero) speeds κ is constant. We give an FPTAS for this case. Again we will use the dual scheduling view and construct a solution in weight space. Notice that in this problem setting, jobs may run at more than one speed. We call those jobs *split jobs*. Our approach is as follows: we first use enumeration to determine split jobs, their position in the weight axis, and the speeds at which they shall run. Then we design an exponential-time DP that fills the remaining jobs running at a single speed into the gaps left between the split jobs. We show then how to reduce the running time of this method to polynomial time by rounding and state cleaning and losing only a small factor in the scheduling cost.

Using a standard scaling argument, we may assume without loss of generality that all job weights have integer values.

5.3.1. Guessing split jobs and partition of the weight axis. Recall that in any optimal solution the speed of the machine is decreasing over time. Thus there are at most $\kappa - 1$ many split jobs each running at a constant number of different speeds. We show that by restricting the set of possible completion weights to a polynomial size, we may guess in polynomial time the subset of split jobs, the speeds at which each of them is running, and their completion weights at an affordable loss in the total cost. The placement of split jobs in the weight axis leads naturally to a partition of the weight axis into (at most) κ intervals to which the remaining nonsplit jobs shall be assigned.

LEMMA 5.5. *By increasing the scheduling cost by at most a factor* $1+\varepsilon$*, we may assume that the completion weights of split jobs are integer powers of* $1+\beta$ *for* $\beta = (1+\varepsilon)^{1/n} - 1$.

Proof. This follows by multiplying the completion weight of each job by $1+\beta$ as in the weight stretch procedure; see section 3. Each time we do this we can decrease the completion weight of one split job to an integer power of $1+\beta$. This increases the total cost by a factor $1+\beta$ each time, which amounts to at most a factor $(1+\beta)^{\kappa-1} < 1+\varepsilon$ for at most $\kappa - 1 < n$ split jobs. ∎

LEMMA 5.6. *By losing at most a factor* $1+\varepsilon$ *in the scheduling cost, we can enumerate in time* $\mathcal{O}(n^{2\kappa-2} \cdot \nu^{\kappa-1})$ *with* $\nu = \lceil \log_{1+\varepsilon} \sum_{j\in J} w_j \rceil$*, the set of split jobs, the speeds at which they run, and their completion weight.*

Proof. The speed of the machine is decreasing and jobs run nonpreemptively. Hence, a split job will run at two or more decreasing speeds $s_i > s_{i+1} > \cdots > s_{i'}$ while there is no other job running at speed s_k with $i < k < i'$. However, not all available speeds might be used. There are $\mathcal{O}(n^{\kappa-1})$ many choices for selecting the set of (at most) $\kappa - 1$ split jobs and the speeds at which each of them is running.

Given a set of jobs we enumerate all possible completion weights for split jobs. Thereby, we restrict it to powers of $1+\beta$ losing at most a factor $1+\varepsilon$ in the cost (Lemma 5.5). There are $\lceil \log_{1+\beta} \sum_j w_j \rceil = \lceil \log_{(1+\varepsilon)^{1/n}} \sum_j w_j \rceil \in \mathcal{O}(n \cdot \nu)$ many possible completion weights per job. Thus, in total we have to consider $\mathcal{O}(n^{\kappa-1} \cdot (n\nu)^{\kappa-1})$ many choices for split jobs with their speeds and positions in the weight axis. ∎

Consider a fixed choice for split jobs $j_1, \ldots, j_{\kappa-1}$ and their completion weights $C^w_{j_1} < C^w_{j_2} < \cdots < C^w_{j_{\kappa-1}}$. For convenience we add dummy jobs with zero weight and work volume if there are less than $\kappa-1$ split jobs. The set of $\kappa-1$ split jobs partitions the weight space into κ subintervals $I_1, \ldots, I_\kappa$ of idle weight between the placed split jobs. More precisely, $I_i = [a_i, a_{i+1} - w_{j_i}]$, where $a_i = C^w_{j_{i-1}}$, for $i \in \{2, \ldots, \kappa\}$, and $a_1 = 0$. Let the last interval I_κ be bounded from above by $\sum_{j\in J} w_j - a_\kappa$. Intervals may also be empty.

To obtain a schedule, we have to fill the remaining jobs nonpreemptively in these idle-weight intervals (keeping the split jobs where they are). All jobs in one subinterval will run at the same speed. Again, recall that the speeds are only decreasing in time which means that they are increasing in weight space. We simply guess the uniform speed s'_i associated with I_i such that $s'_1 \le s'_2 \le \cdots \le s'_\kappa$ in accordance with the speeds of the split jobs between intervals, i.e., for each speed s for a split job j_i separating intervals I_i and I_{i+1} must satisfy $s'_i \le s \le s'_{i+1}$. Notice that because of the dummy jobs there might be more than one interval with the same speed.

COROLLARY 5.7. *By losing at most a factor* $1+\varepsilon$ *in the scheduling cost we can reduce in time* $\mathcal{O}(\kappa^\kappa \cdot n^{2\kappa-2} \cdot \nu^{\kappa-1})$ *the speed-scaling problem to nonpreemptive scheduling in weight space in a given set of available idle-weight intervals* $I_1, I_2, \ldots, I_\kappa$ *and speed* s'_i *for jobs being assigned to* I_i.

5.3.2. Dynamic program. We construct a DP that finds a partition of the set of nonsplit jobs into κ subsets each of which is assigned to an individual interval I_i. The jobs in each individual set are scheduled according to the Reversed Smith rule in weight space, that is, in nondecreasing order of ratios w_j/v_j. Let all jobs be indexed in this order.

The DP generates a state $[k, z, y_1, \ldots, y_\kappa]$ if there is a feasible schedule of jobs $1, \ldots, k$, in which the total weight scheduled in interval I_i (excluding the split job) is

y_i. The total scheduling cost (including split jobs) is $z := \sum_{j=1}^{k} x_j C_j^w$ with $x_j = v_j/s'_i$ being the execution time of a job j in interval i. The value of the state $[k, z, y_1, \ldots, y_\kappa]$ is the minimum energy that is necessary for obtaining such a schedule. The DP starts with the states $[0, z, 0, \ldots, 0]$. For each z-value an LP computes the minimum energy that is necessary to obtain this scheduling value when scheduling only the set of split jobs J_s. It determines the power assigned to each split job and thus their actual execution times. Let ℓ_{ji} be the amount of time that split job $j \in J_s$ is running at a valid speed s'_i (given by Lemma 5.6):

$$\begin{aligned}
&\min \sum_{j \in J_s} \sum_{i=1}^{\kappa} \ell_{ji} P(s'_i), \\
&\sum_{j \in J_s} C_j^w \cdot \sum_{i=1}^{\kappa} \ell_{ji} \le z, \\
&\sum_{i=1}^{\kappa} \ell_{ji} s'_i = v_j && \text{for all } j \in J_s, \\
&\ell_{ji} \ge 0 && \text{for all } j \in J_s, i \in \{1, \ldots, \kappa\}, \\
&\ell_{ji} = 0 && \text{for all } j \in J_s,\ s'_i \text{ not valid for } j\,.
\end{aligned}$$

After computing the starting states, the DP computes all states by moving from any state $[j-1, z, y_1, \ldots, y_\kappa]$ to at most κ new states $[j, z', y'_1, \ldots, y'_\kappa]$ by assigning job j to intervals I_i for $i \in \{1, \ldots, \kappa\}$. Then

$$z' = z + \frac{v_j}{s'_i} \cdot (a_i + y_i + w_j) \text{ and } y'_i = y_i + w_j \text{ and } y'_{i'} = y_{i'} \text{ for } i' \neq i\,, \tag{5.3}$$

provided that $y'_i \le |I_i| - w_{j_i}$, where j_i is the ith split job. The value of the new state is

$$E[j, z, y_1, \ldots, y_\kappa] = E[j-1, z, y_1, \ldots, y_\kappa] + \frac{v_j}{s'_i} \cdot P(s'_i). \tag{5.4}$$

If there exists another state with less energy value,

$$E'[j, z, y_1, \ldots, y_\kappa] < E[j, z, y_1, \ldots, y_\kappa],$$

we discard the new one with larger energy value.

An optimal schedule can be obtained by finding a state $E[n, z, y_1, \ldots, y_\kappa] \le E$ with minimum z and backtracking from that state. Since the z-values are bounded by $z_{UB} := \sum_{j=1}^{n} w_j (\sum_{\ell=1}^{j} v_\ell / s_\kappa)$ and the y_i-values are bounded by $|I_i|$, the running time of this dynamic programming algorithm is $\mathcal{O}(n \cdot z_{UB} \cdot \max_i |I_i|^\kappa)$.

5.3.3. Rounding. In a fully polynomial time algorithm, we can neither afford to consider all possible objective values z, nor can we consider all possible y_i-values.

Consider first the number of possible values z of scheduling cost. We round them the same way as we have done in the PTAS for an arbitrary number of discrete speeds in Theorem 5.2. Given the upper bound on the cost, $z_{\mathrm{UB}} = \sum_{j=1}^{n} w_j (\sum_{\ell=1}^{j} v_\ell / s_\kappa)$, we can reduce the number of possible values in $z \in [0, z_{\mathrm{UB}}]$ to $\mathcal{O}(\nu \cdot \log z_{\mathrm{UB}}/\varepsilon) = \mathcal{O}(\nu \cdot n/\varepsilon^2)$ by restricting it to powers of $1+\delta$ with $\delta = (1+\varepsilon)^{1/\nu} - 1$ and lose only a factor $1+\varepsilon$ in the scheduling cost. Recall that $\nu = \lceil \log_{1+\varepsilon} \sum_{j \in J} w_j \rceil$. Let DP_z denote this DP that rounds only the scheduling cost.

We now take care of the y-values. The idea is to reduce the number of states by removing those with the same (rounded) objective value and nearly the same total

weight in all intervals I_i. Among them, we store those that require the minimum amount of energy. To do so, we use the same discretization of the weight axis as for guessing the completion weights of split jobs (section 5.3.1). When the DP adds a job j to some interval I_i and updates the total weight $y_i' = y_i + w_j$ (see (5.3)) then we store only the information on y_i' rounded down to the closest integer power of $1+\beta$ with $\beta = (1+\varepsilon)^{1/n} - 1$. Now, among all states with the same rounded values $z, y_1, \ldots, y_\kappa$ we store the one with minimum energy consumption. Let $\mathrm{DP}_{z,y}$ denote the modified DP that rounds z- and y-values.

Rounding down the y_i-values will incur an error in the computation of scheduling cost; more precisely, interpreting the solution of $\mathrm{DP}_{z,y}$ as a job (weight) assignment to intervals, then the y-values stored for describing a DP state underestimate the true weight assigned to an interval, and thus, the DP also underestimates the total scheduling cost z. We have to show in the following that this error is small compared to the true value of a feasible solution. We will also show that the energy consumption computed by the DP corresponds to the exact energy required in a feasible solution.

LEMMA 5.8. *Suppose that algorithm* DP_z *on an instance with* n *jobs finds a chain of states*[3] $[0, z_0^*, 0, \ldots, 0], [1, z_1^*, y_{1,1}^*, \ldots, y_{\kappa,1}^*], \ldots, [n, z_n^*, y_{1,n}^*, \ldots, y_{\kappa,n}^*]$. *Then the algorithm* $\mathrm{DP}_{z,y}$ *finds for each job* $j \in \{1, \ldots, n\}$ *a state of the form* $[j, z_j, y_{1,j}, \ldots, y_{\kappa,j}]$ *of energy value at most* $E[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*]$ *such that*

$$y_{i,j} \le y_{i,j}^* \qquad \text{and} \qquad z_j \le z_j^*. \tag{5.5}$$

Proof. We give a proof by induction on the number of jobs j. For $j = 0$ the property is clearly true since $\mathrm{DP}_{z,y}$ and DP_z have the same starting states.

Suppose the lemma is true for j jobs, and $\mathrm{DP}_{z,y}$ obtains state $[j, z_j, y_{1,j}, \ldots, y_{\kappa,j}]$ satisfying the properties of the lemma. Now consider state $[j+1, z_{j+1}^*, y_{1,j+1}^*, \ldots, y_{\kappa,j+1}^*]$ that DP_z obtained from $[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*]$ according to (5.3) by adding job $j+1$ to interval I_i, for some $i \in \{1, \ldots, \kappa\}$. Similarly, starting from $[j, z_j, y_{1,j}, \ldots, y_{\kappa,j}]$, Algorithm $\mathrm{DP}_{z,y}$ considers a state that inserts job $j+1$ to interval I_i. This yields a new state $[j+1, z_{j+1}, y_{1,j+1}, \ldots, y_{\kappa,j+1}]$ that satisfies $z_{j+1} = z_j + v_{j+1}/s_i' \cdot (a_i + y_{i,j} + w_{j+1})$ and $y_{i,j+1}$ as $\bar{y}_{i,j+1} = y_{i,j} + w_{j+1}$ rounded down to the nearest power of $1+\beta$, while it keeps $y_{i',j+1} = y_{i',j}$ for all $i' \neq i$.

By the inductive hypothesis, we have that $y_{i,j} \le y_{i,j}^*$ and thus

$$z_{j+1} = z_j + v_{j+1}/s_i' \cdot (a_i + y_{i,j} + w_{j+1}) \le z_{j+1}^*.$$

Moreover, since we round down the value $\bar{y}_{i,j+1}$ to $y_{i,j+1}$ we obtain that

$$y_{i,j+1} \le \bar{y}_{i,j+1} = y_{i,j} + w_{j+1} \le y_{i,j}^* + w_{j+1} = y_{i,j+1}^*.$$

It remains to argue on the value of the state, that is, the energy cost. According to (5.4) the value of the state as computed by $\mathrm{DP}_{z,y}$ is

$$\begin{aligned} E[j+1, z_{j+1}, y_{1,j+1}, \ldots, y_{\kappa,j+1}] &= E[j, z_j, y_{1,j}, \ldots, y_{\kappa,j}] + \frac{v_{j+1}}{s_i'} \cdot P(s_i') \\ &\le E[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*] + \frac{v_{j+1}}{s_i'} \cdot P(s_i') \\ &= E[j+1, z_{j+1}^*, y_{1,j+1}^*, \ldots, y_{\kappa,j+1}^*]. \end{aligned}$$

[3] *Chain* of states means that, for $j = 0, \ldots, n-1$, state $[j+1, z_{j+1}^*, y_{1,j+1}^*, \ldots, y_{\kappa,j+1}^*]$ is obtained from $[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*]$ by adding job $j+1$ according to (5.3).

We cannot guarantee that state $[j+1, z_{j+1}, y_{1,j+1}, \ldots, y_{\kappa,j+1}]$ survives. But in case it does not then we have found another partial solution with the same objective value z_{j+1}, the same values $y_{i,j+1}$, and an even smaller state value (energy). This concludes the lemma. ∎

The Algorithm $\mathrm{DP}_{z,y}$ computes an assignment of jobs to weight intervals but it underestimates the total weight assigned to an interval and thus the scheduling cost. We show that the true scheduling cost when scheduling according to the solution found by $\mathrm{DP}_{z,y}$ is bounded.

LEMMA 5.9. *Suppose that algorithm* $\mathrm{DP}_{z,y}$ *on an instance with* n *jobs finds a chain of states* $[0, z_0^*, 0, \ldots, 0], [1, z_1^*, y_{1,1}^*, \ldots, y_{\kappa,1}^*], \ldots, [n, z_n^*, y_{1,n}^*, \ldots, y_{\kappa,n}^*]$. *Then for each state* $[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*]$, *with* $j \in \{1, \ldots, n\}$, *there exists a feasible partial schedule of split jobs and jobs* $1, \ldots, j$ *using an energy budget of at most* $E[j, z_j^*, y_{1,j}^*, \ldots, y_{\kappa,j}^*]$. *Moreover, if* $y_{i,j}$ *denotes the total weight of jobs assigned to interval* I_i *in the partial schedule and* z_j *is the scheduling cost, then*

$$y_{i,j} \leq (1+\beta)^j \cdot y_{i,j}^* \qquad \text{and} \qquad z_j \leq (1+\beta)^j \cdot z_j^* \,. \tag{5.6}$$

Proof. We give a proof by induction on j. By definition of the starting state $[0, z_0^*, 0, \ldots, 0]$ there exists a partial schedule of the split jobs with cost at most z_0^*. Thus the base case of the induction follows.

For a given j, assume that the DP obtains state $[j+1, z_{j+1}^*, y_{1,j+1}^*, \ldots, y_{\kappa,j+1}^*]$ by adding job $j+1$ to interval I_i. By the induction hypothesis suppose that there exists a partial schedule satisfying the claim for jobs $1, \ldots, j$. We construct the new schedule for jobs $1, \ldots, j+1$ by also adding $j+1$ to I_i. The total weight assigned to interval I_i in this solution is

$$y_{i,j+1} = y_{i,j} + w_{j+1} \leq (1+\beta)^j \cdot y_{i,j}^* + w_{j+1} \leq (1+\beta)^j \cdot (y_{i,j}^* + w_{j+1}).$$

Since $\mathrm{DP}_{z,y}$ rounds down the y-value to the next integral power of $1+\beta$, we have that

$$y_{i,j+1}^* \geq \frac{1}{1+\beta} \cdot \left(y_{i,j}^* + w_{j+1}\right).$$

And thus we conclude $y_{i,j+1} \leq (1+\beta)^{j+1} \cdot y_{i,j+1}$.

Consider now the total scheduling cost of the feasible schedule after adding job $j+1$. In principle it consists of the scheduling cost z_j before adding job $j+1$ plus the cost for the new job. However there is a possible extra source for error. Since the DP rounded down y-values, we cannot guarantee that the total weight assigned to an interval I_i actually fits into this interval. (Recall, that these intervals are defined by the placement of the split jobs in the weight axis which is in principle flexible.) Thus, we may increase the completion weight of already assigned jobs by at most a factor $1+\beta$ which means increasing z_j by this factor. Then, by again using the induction hypothesis and the already proven first condition in (5.6) we get

$$\begin{aligned} z_{j+1} &\leq (1+\beta) \cdot z_j + v_{j+1}/s_i' \cdot (a_i + y_{i,j} + w_{j+1}) \\ &\leq (1+\beta)^{j+1} \cdot z_j^* + v_{j+1}/s_i' \cdot (a_i + (1+\beta)^j \cdot y_{i,j}^* + w_{j+1}) \\ &\leq (1+\beta)^{j+1} \cdot \left(z_j^* + v_{j+1}/s_i' \cdot (a_i + y_{i,j}^* + w_{j+1})\right) = (1+\beta)^{j+1} \cdot z_{j+1}^*. \end{aligned}$$

Concerning the energy estimation, recall that the DP determined the energy cost precisely according to (5.4). Thus, an inductive argument shows that the constructed schedule incurs the same energy consumption. ∎

Now we can prove the main result.

THEOREM 5.10. *There is an FPTAS for speed-scaling with a given energy budget for* $\min \sum w_j C_j$ *on a single machine with constantly many discrete speeds.*

Proof. The FPTAS is as follows: we guess the split jobs, their speeds, and positions which gives us a partition of the weight space into κ idle-weight intervals (see section 5.3.1). Then we run $\mathrm{DP}_{z,y}$ and take as final solution the assignment of jobs to intervals that the DP computes.

Let OPT denote the scheduling cost of an optimal solution, and let $z(A)$ denote the scheduling cost of a solution computed by algorithm A. Lemma 5.8 guarantees that $\mathrm{DP}_{z,y}$ finds a final state of cost $z(\mathrm{DP}_{z,y}) \leq z(\mathrm{DP}_z)$. We can argue that $z(\mathrm{DP}_z) \leq (1+\varepsilon)^2\mathrm{OPT}$ because we lose one factor $1+\varepsilon$ when guessing the split jobs (Lemma 5.6) and another factor $1+\varepsilon$ when rounding the z-values in DP_z. Taking the assignment of jobs to intervals as computed by $\mathrm{DP}_{z,y}$, we obtain a feasible scheduling solution of cost $z_n \leq (1+\beta)^n z(\mathrm{DP}_{z,y}) \leq (1+\varepsilon)z(\mathrm{DP}_{z,y})$, where $\beta = (1+\varepsilon)^{1/n} - 1$ (Lemma 5.9). Thus, we find a feasible solution of scheduling cost at most $(1+\varepsilon)^3\mathrm{OPT}$.

Furthermore, Lemmas 5.8 and 5.9 guarantee that our final solution uses as much energy as an optimal solution. Thus we stay within the energy bound.

It remains to show that the running time is polynomial in the input and $1/\varepsilon$. By Lemma 5.6 the enumeration step leading to the partitioning of the weight axis takes time $\mathcal{O}(\kappa^\kappa \cdot n^{2\kappa-2} \cdot \nu^{\kappa-1})$ with $\nu = \lceil \log_{1+\varepsilon} \sum_{j\in J} w_j \rceil$. The original (exponential time) DP runs at time $\mathcal{O}(n \cdot z_{UB} \cdot \max_i |I_i|)$ (see section 5.3.2). Algorithm $\mathrm{DP}_{z,y}$ rounds the z- and y-values and with the argumentation in section 5.3.3 it thus runs in time $\mathcal{O}(n \cdot (\nu \cdot n/\varepsilon^2) \cdot (n \cdot \nu)) = \mathcal{O}(n^3/\varepsilon^2 \cdot \nu^2)$. Since we run the DP for each guess of split jobs, we obtain a total running time $\mathcal{O}(\kappa^\kappa \cdot n^{2\kappa+1}/\varepsilon^2 \cdot \nu^{\kappa+1})$ which is polynomial in the input and $1/\varepsilon$. ∎

6. Speed-scaling with release dates on multiple machines. We can use our results obtained in the dynamic-speed setting to approximate the more general problem of preemptively scheduling jobs with nontrivial release dates on identical parallel machines. We use the fact that we can handle jobs without release dates on a single machine and apply a *fast single machine relaxation* [10]. For the relaxation, we assume that we have a single machine that is m time faster than one of the original machines: at a power level p the single machine runs at speed $m \cdot p^{1/\alpha}$, while at the same power level one of the original machines runs at speed $p^{1/\alpha}$. Thus, if an amount of energy E_j for job j implies a execution time of x_j on an original machine, then the same energy implies an execution time of x_j/m on the fast single machine.

After using our PTAS to solve the single machine relaxation without release dates, we keep the energy assignments E_j computed in the relaxation and apply standard *preemptive list scheduling* on parallel machines respecting release dates. However, the difficulty lies in bounding the actual execution times x_j in our final solution, since we do not have any information about the optimal execution times x_j^*.

The trick we use is as follows: suppose we knew the total weighted value of execution times in an optimal schedule $\sum_{j\in J} w_j x_j^* = X^*$. Then it is easy to verify that the fast single machine relaxation with the *additional constraint* $\sum_{j\in J} w_j m x_j^1 \leq X^*$ on the weighted actual executions times x_j^1 on the fast machine still gives a lower bound. Consider the problem of scheduling a job set J (with release dates) on m parallel machines using an energy budget E. Let $Z(X^*)$ be the cost of an optimal schedule using energy E and $\sum_{j\in J} w_j x_j^* = X^*$. Consider an optimal preemptive schedule with cost $Z_1(X^*)$ for J without release dates on a single machine of speed m with energy E and the additional constraint $\sum_{j\in J} w_j m x_j^1 \leq X^*$.

LEMMA 6.1. $Z_1(X^*) \leq Z(X^*)$.

Proof. The proof goes along the same lines as in the nonenergy setting in [10]. Using time discretization, any parallel machine schedule can be converted into a feasible preemptive schedule on a fast single machine without increasing the total cost and without changing the total energy given to each job. Thus, an optimal single machine schedule gives a lower bound. ∎

Given X^*, we can solve the restricted fast single machine relaxation using the PTAS from Theorem 4.4 (continuous speeds) or Theorem 5.2 (discrete speeds), respectively. We can directly implement the additional constraint of restricting the total weighted execution time by adding an entry to the corresponding dynamic programming table which tracks this value for each partial solution. To guarantee polynomial running time, we round the values to powers of $1+\varepsilon$ at the cost of an additional factor $1+\varepsilon$ in the approximation guarantee.

The solution of the fast single machine relaxation gives a priority ordering for the preemptive list scheduling algorithm to obtain the final parallel machine solution. It remains the issue that we do not know X^*. Essentially, we run the algorithm (fast single machine relaxation plus preemptive list scheduling) for every possible value $X^* \in [X_L, X_U]$ for some upper and lower bounds X_L, X_U that we define below, and we pick the best feasible solution. Again, to guarantee a polynomial running time we choose only values that are powers of $1+\varepsilon$ at the cost of a small increase in the approximation guarantee.

A simple lower bound on X^* is obtained by giving each job the maximum amount of energy E. Recall that $x_j = (v_j^\alpha / E_j)^{1/(\alpha-1)}$. Thus,

$$X^* = \sum_{j \in J} w_j x_j^* \geq \sum_{j \in J} w_j \left(\frac{v_j^\alpha}{E}\right)^{\frac{1}{\alpha-1}} =: X_L \,.$$

An upper bound can be obtained as follows: the optimal execution times x_j^* are bounded by the completion times in an optimal solution and, thus, $X^* \leq \text{OPT}$. The value OPT obtained on multiple machines is not larger than the optimal solution for the same job set and energy using just a single machine. Now, for the cost of an optimal single machine solution we gave an explicit expression in (4.3). This expression used a solution-dependent remaining weight parameter W_j which we crudely bound by $n \cdot w_{max}$ with $w_{\max} := \max_{j \in J} w_j$. We obtain

$$\begin{aligned} X^* \leq \text{OPT} &\leq \frac{1}{E^{\frac{1}{\alpha-1}}} \cdot \left(\sum_{j=1}^{n} v_j \cdot (n \cdot w_{\max})^{\frac{\alpha-1}{\alpha}}\right)^{\frac{\alpha}{\alpha-1}} \\ &= \frac{n \cdot w_{\max}}{E^{\frac{1}{\alpha-1}}} \cdot \left(\sum_{j=1}^{n} v_j\right)^{\frac{\alpha}{\alpha-1}} =: X_U \,. \end{aligned}$$

A summary of the algorithm is given below.

THEOREM 6.2. Fast-Relax+List-Scheduling *is a factor* $2+\varepsilon$ *approximation for continuous and discrete speed-scaling when jobs have individual release dates.*

Proof. Let X^* be the total weighted execution time in an optimal parallel machine schedule with cost OPT. Let $\varepsilon' := \varepsilon/2$, and let X' satisfy $X^* \leq X' \leq (1+\varepsilon')X^*$. The algorithm returns the minimum cost solution over all weighted completion time

Algorithm 6.1 Algorithm Fast-Relax+List-Scheduling.

Let $\varepsilon' := \varepsilon/2$.

1: **for** $i = 0$ to $\lceil \log_{1+\varepsilon'} X_U/X_L \rceil$ **do**
2: Let $X = (1+\varepsilon')^i$.
3: Compute an energy assignment E_j and a scheduling solution π for the given job set J with release dates set to 0 on a single machine running m times as fast as the original machines, with energy budget E, and respecting the additional constraint that $\sum_{j\in J} w_j \cdot mv_j/s_j \le X$. If there is no solution, then $i \leftarrow i+1$.
4: Keep the energy assignment and apply preemptive list scheduling according to π on m machines respecting release dates, i.e., run at any time the m jobs with the highest priority in π among the available (released, unfinished) jobs.
5: If the total cost of this solution is less than previous solutions then keep it, otherwise disregard.
6: $i \leftarrow i+1$.
7: **end for**

bounds X. Thus, the cost of the final solution is bounded by the total cost of the solution obtained based on X'. We show that the cost of this solution is at most $2(1+\varepsilon')\text{OPT} = (2+\varepsilon)\text{OPT}$.

Let $Z_1(X)$ denote the cost of an optimal solution to the fast single machine problem with imposed constraint $\sum_{j\in J} w_j \cdot mv_j/s_j \le X$. Clearly, $Z_1(X') \le Z_1(X^*)$. Let $C_j^1(X')$ denote the completion time of job j in a solution to the the fast single machine problem with imposed constraint X' when applying a PTAS (Theorem 4.4 for continuous speeds or Theorem 5.2 for discrete speeds, respectively). Lemma 6.1 and the observation above imply

$$\sum_{j\in J} w_j C_j^1(X') \le (1+\varepsilon')Z_1(X') \le (1+\varepsilon')Z_1(X^*) \le (1+\varepsilon')\text{OPT}\,.$$

Now consider the final list scheduling solution obtained for bound X', and let C_j denote the completion time of a job j. Recall that the algorithm keeps the energy assignment from the fast single machine relaxation; thus, the execution time of a job j is $x_j = m \cdot x_j^1$, where x_j^1 is the actual execution time of j on the fast single machine. By construction, a job j starts only processing when the first machine becomes available after its release date and after starting all jobs k with higher priority in π (denoted by $k <_\pi j$). Thus, its completion time is bounded by $C_j \le r_j + \sum_{k<_\pi j} x_k/m + x_j$. Thus, the total cost of the algorithms solution ALG is

$$\begin{aligned}
\text{ALG} &\le \sum_{j\in J} w_j r_j + \sum_{j\in J} w_j \sum_{k<_\pi j} x_j^1 + \sum_{j\in J} w_j x_j \\
&\le \sum_{j\in J} w_j r_j + \sum_{j\in J} w_j C_j^1(X') + \sum_{j\in J} w_j \cdot m x_j^1 \\
&\le \sum_{j\in J} w_j r_j + (1+\varepsilon')\text{OPT} + \sum_{j\in J} w_j \cdot m x_j^1.
\end{aligned}$$

Now, by construction we have that $\sum_{j\in J} w_j \cdot m x_j^1 \le X' \le (1+\varepsilon')X^*$. Using, the obvious lower bound $\text{OPT} \ge \sum_{j\in J} w_j r_j + X^*$, we conclude $\text{ALG} \le 2(1+\varepsilon')\text{OPT}$. ∎

7. Conclusion. In this paper we have demonstrated the power of a dual scheduling view for minimizing the total weighted completion time—in particular, when

scheduling on a machine that may change its speed. Instead of the standard approach of scheduling along the time axis, we schedule jobs in the weight axis of the well-known 2D Gantt chart. This change of concept allows us to handle the complexity of machine speed changes. We give several algorithms relying on dual techniques and show that they guarantee nearly optimal solutions. Most of our results are best possible in terms of approximation guarantees.

An interesting open question is how to incorporate release dates for the varying-speed scenario and improve the $(4+\varepsilon)$-approximation in [14]. While with our current technique we can almost fully resort to the weight space, release dates would require maintaining a correspondence between weight and time space.

The most challenging open problem in this context concerns min-sum scheduling when each job may have its own nondecreasing cost function f_j. Any improvement of the recent $(4+\varepsilon)$-approximation [11] for $1|\,|\sum f_j$ would be of significant interest. Our PTAS on a machine of varying speed translates into the equivalent setting of scheduling on a unit-speed machine to minimize a general global cost function $\sum w_j f(C_j)$ and thus is a tight result for this case.
